Dampening General Equilibrium*

George-Marios Angeletos† Chen Lian‡

April 30, 2017

Abstract
We formalize the notion that GE adjustment is weak, or that it takes time, by modifying an elementary Walrasian economy in two alternative manners. In one, we maintain rational expectations but remove common knowledge of aggregate shocks and accommodate higher-order uncertainty. In the other, we replace Rational Expectations Equilibrium with solution concepts that mimic Tâtonnement or Cobweb dynamics, Level-k Thinking, and Cognitive Discounting. We show how these modifications amount to attenuating GE feedbacks and explain why they, contrary to pure noise, can generate either under- or over-reaction in aggregate outcomes.

Keywords: Partial Equilibrium, Tâtonnement, Cobweb, Level-k Thinking, Reflective Equilibrium, Incomplete Information, Coordination, Beauty Contests.

---

*This paper subsumes an earlier draft that contained a similar message but used a different framework. We are grateful to Guido Lorenzoni for a conference discussion of our paper, and to Martin Beraja, Adam Guren, Alessandro Pavan, and Muhamet Yildiz for helpful comments. We also thank seminar participants at MIT, Chicago Booth, Duke, the Iowa State Conference on Global Games, the EFCE group at the 2016 NBER Summer Institute, and the 2016 ESEM in Edinburgh.

1 Introduction

General-equilibrium (GE) effects—and the presumed ability of economic agents to foresee these effects—are key to interpreting macroeconomic outcomes and guiding policy. In some contexts, they reinforce partial-equilibrium (PE) effects, acting as “macroeconomic multipliers” that amplify exogenous shocks or raise policy effectiveness. In other contexts, they offset PE effects, helping stabilize aggregate outcomes or curtailing policy effectiveness. Either way, GE mechanisms limit the usefulness of PE intuitions. For instance, the popular notion that a reduction in demand can trigger a recession may appear to be self-evident from a PE perspective, yet it finds no place in the neoclassical/RBC framework because of countervailing GE effects.

GE effects also limit the usefulness of a growing empirical literature that seeks to quantify the causal effects of aggregate shocks by exploiting the cross-sectional heterogeneity in the exposure to such shocks. For instance, consider Mian and Sufi (2014). This work offers compelling evidence that US regions that experienced steeper drops in consumer credit during the recent recession also experienced larger employment losses. This evidence is suggestive of the role that consumer deleveraging may have played at the aggregate level. There is, however, an important limitation. GE effects such as the adjustment of prices and income at the national level are absorbed by the time fixed effect of the considered regressions. As a result, there is a gap—of unknown magnitude and sign—between the “local” or “micro” elasticities that are estimated in this kind of work and the macroeconomic effects that are ultimately of interest.

In this paper, we argue that standard modeling practice often exaggerates the potency of GE mechanisms. In particular, we explain the sense in which the combination of a strong solution concept and strong informational assumptions “maximizes” the ability of economic agents to foresee certain GE implications of any given aggregate shock, thus also maximizing the GE effects of the shock. We do so by exploring multiple formalizations of the notion that GE adjustment may be “weak” or “slow”. All but one of them replace Rational Expectations Equilibrium (REE) with solution concepts that can be thought of as forms of “bounded rationality”. Our preferred alternative, on the other hand, maintains rational expectations but removes common knowledge of aggregate shocks.

This multifaceted approach serves two goals. On the applied front, we offer multiple justifications for why GE adjustment may be weaker or slower than what previously considered. In settings in which GE effects amplify PE effects, this manifests as under-reaction and inertia at the aggregate level. In settings in which, instead, GE effects offset PE effects, it manifests as over-reaction and overshooting. In either case, because the underlying decision rules and the relevant PE effects remain unchanged, the gap between the relevant micro and macro elasticities is reduced.\(^1\)

On the methodological front, on the other hand, we help connect the literature on incomplete information reviewed in Angeletos and Lian (2016b), an older tradition that used Tâtonnement or Cobweb dynamics to sought to capture the off-equilibrium adjustment of prices in Walrasian economies, a recent literature that studies monetary policy without rational expectations,\(^2\) and some of our own work. We are thus able to elaborate on the capacity of different modeling approaches to attenuate or slow down GE adjustment, as well as to explain the sense in which lack of common knowledge can be seen as a useful substitute to bounded rationality.

Framework. We consider an elementary Walrasian economy, featuring decentralized and sequential trading. There is a large number of “marketplaces”, which define the boundaries of market interactions: every agent can trade in a single marketplace in each period, but may randomly be relocated from one marketplace to another as time passes.

These are stark assumptions, which nevertheless capture two basic facts: that most trading is decentralized; and that agents face uncertainty about their future interactions with agents they do not currently trade with.\(^3\) Moreover, these

---

\(^1\) Throughout, the term “elasticity” refers to the response of an equilibrium outcome to an exogenous shock. In dynamic settings, the corresponding concept is an impulse response function. Also, “micro” refers to the level of a market or a region, “macro” to the level of the economy.

\(^3\) In these respects, our modeling strategy borrows from the literatures on decentralized trading, the search-theoretic foundations of money, and OTC markets (e.g., Townsend, 1980; Kiyotaki and Wright, 1993; Lagos and Wright, 2005; Gale, 1986; Golosov, Lorenzoni, and Tsyvinski, 2014; Duffie, Garleanu, and Pedersen, 2005). The issue under consideration, however, is distinct.
assumptions help us draw a clear line between partial and general equilibrium: the former refers to the adjustment of a single marketplace in isolation of the rest of the economy, the latter refers the joint adjustment of all the marketplaces.

Starting from a status quo, we let an exogenous shock change the economy’s fundamentals (preferences, technologies, and endowments) and ask how its outcomes (quantities and prices) adjust to the shock. The answer to this question depends on two sets of assumptions. The first governs how the shock impacts the demand, the supply, and the market-clearing outcomes in any given marketplace, taking as given the local perceptions of the behavior and the prices in other marketplaces. The second specifies how these perceptions themselves adjust to the shock.

In our analysis, we fix the first set of assumptions in line with standard modeling practice, but modify the second set. In so doing, we are able to vary the potency of the GE effects of the shock, while holding constant its PE effects.

**Frictionless Benchmark.** In the vast majority of applied work, the relevant set of assumptions is (i) rational expectations and (ii) common knowledge of the state of the economy. This combination defines our frictionless benchmark. Our benchmark predicts certain micro and macro elasticities, which serve as reference points in our subsequent analysis. The macro elasticity measures the total effect of an aggregate shock on an aggregate outcome. The micro elasticity measures the total effect of a local shock on the outcome of a single marketplace or, equivalently, the PE effect of the aggregate shock. The gap between the two elasticities encapsulates the GE effect of the aggregate shock.

Our benchmark also has the following quality: it replicates the outcomes of an Arrow-Debreu variant that allows the agents to trade a complete set of date- and state-continent trades in a single centralized market that operates once, at the beginning of time. Although not strictly needed for our purposes, this property is useful for three reasons. First, it clarifies that our choice to let trading be sequential and decentralized does not introduce a friction by itself. Second, it relates the conjectures that the agents form in our setting to the prices they observe in the Arrow-Debreu variant. Finally, it sharpens the sense in which the GE adjustment is “perfect” and “instantaneous” in our benchmark.

All the considered modifications seek to relax this kind of perfection in the GE adjustment to the aggregate shock. This is achieved by dropping either (i) rational expectations or (ii) the assumption that the shock is common knowledge.

**Tâtonnement.** Our first modification lets the conjectures that the agents form about the likely GE effects of the shock be the product of an algorithm that mimics Tâtonnement dynamics. We choose this starting point because Tâtonnement dynamics was traditionally meant to capture the process of adjustment from one equilibrium point to another. Unlike the textbook version of this concept, however, there is no actual dynamics: we only model a cognitive process via which each agent forms conjectures about market outcomes she does not directly observe. This process mimics a Walrasian auctioneer who bases an initial conjecture on the pre-shock equilibrium point; computes the implied gap between demand and supply; adjusts the relevant conjecture accordingly; and iterates. The number of iterations is interpreted as the agent’s “depth of reasoning”.

In our framework, this cognitive process is equivalent to iterating on a contraction mapping, whose fixed point pins down the REE prices. It follows that, in the limit as the depth of the process becomes infinite, the post-shock price conjectures coincide with their frictionless counterparts. But as long as the agents are “bounded rational” in the sense that the aforementioned depth is finite, the assumed cognitive process generates a weaker adjustment in the relevant conjectures than rational expectations do. It is therefore as if the GE spillovers have been reduced. Indeed, in the limit that corresponds to zero cognitive depth, the macroeconomic effect of the shock is given by the PE effect alone: each marketplace responds to the aggregate shock as if it were an idiosyncratic shock.

This result offers our first formalization of the sought-after notion that GE adjustment is “imperfect” or “weak”, relative to the frictionless benchmark. Because the PE adjustment that takes place at the marketplace level remains the same as in that benchmark, the gap between the micro and macro elasticities of interest is reduced. The caveat is that, by design, this comes at the cost of violating rational expectations.

---

4This excludes, of course, the literatures reviewed in Angeletos and Lian (2016b) and Woodford (2013).
5This terminology perhaps evokes game-theoretic concepts such as Level-k Thinking. We study the connection in the sequel.
**Lack of Common Knowledge.** Our second modification bypasses the aforementioned caveat by imposing rational expectations. It nevertheless attenuates the GE adjustment by relaxing the assumption that the agents have common knowledge of the shock and of the outcomes of marketplaces they do not themselves participate in.

While conceptually distinct, this modification is shown to have similar observable implications as the one based on Tâtonnement dynamics. In particular, we establish the following observational-equivalence result: for any depth of reasoning in the Tâtonnement-based economy, there is a level of common knowledge in the new variant such that the irrational conjectures in the former are recast as the average rational expectations in the latter, and the two economies generate the same observables at the aggregate level; and vice versa.

We conclude that, in our framework, lack of common knowledge helps rationalize a more ad hoc, and old-fashioned, way of thinking about equilibrium adjustment. But we also obtain the following distinct prediction: the larger the GE effect in the frictionless benchmark, the larger the fraction of this effect that gets “erased” by any given level of informational friction. In this regard, the offered remedy to the disconnect between the micro and the macro elasticities of interest appears to work better when the disconnect is the more severe to start with. Last but not least, we show that lack of common knowledge attenuates GE effects regardless of whether they reinforce or offset PE effects—a prediction that, as discussed next, is not shared by some of the considered alternatives.

All these predictions are driven by the following basic insight. Regardless of the information structure, rational expectations impose a fixed-point relation between actual and expected outcomes. The nature and the observable properties of this fixed point, however, depend crucially on the level of common knowledge. This is because this fixed point is itself pinned down, not only by what the agents know about the underlying shock, but also by their higher-order beliefs—what they think that others know, and so on. As one varies the degree of such higher-order knowledge, one also varies the potency of the GE effect of the underlying shock.

Having said that, one does not have to get lost in the wilderness of higher-order beliefs. The main point can be recast as follows. The rational-expectations hypothesis alone does not nail down the relevant GE effect; it only restricts its (absolute) magnitude within an interval. By imposing rational expectations together with perfect common knowledge, standard practice picks, perhaps inadvertently, the upper bound of this interval. We instead show how one can span the entire interval by varying the degree of common knowledge. In this regard, we complement Bergemann and Morris (2013), who study a class of beauty-contest games under arbitrary information structures; most importantly, we explain the precise sense in which standard practice has “overstated” the importance of GE mechanisms.

**Near-rationality, Cobweb, Level-k Thinking, and more.** Unlike our Tâtonnement-based variant, other plausible forms of “bounded rationality” may fail to capture the sought-after notion of GE attenuation. Consider, for example, the near-rationality concept of Akerlof and Yellen (1985a) or that of $\epsilon$-equilibrium in games. Adapting these concepts to our framework allows the modified macro elasticity to vary within a neighborhood of its frictionless counterpart, but does not restrict the relation between the two—the GE effect can be either attenuated or amplified.

We thus investigate whether GE attenuation is predicted by four other kinds of bounded rationality. The first mimics Cobweb dynamics. The second utilizes an auxiliary result, which represents our Walrasian economy as a game, and applies Level-k Thinking (Nagel, 1995, Stahl and Wilson, 1995). The third considers Reflective Equilibrium, a concept developed by Garcia-Schmidt and Woodford (2015). The fourth mimics the belief bias assumed in Gabaix (2016).²

The variant based on Cobweb dynamics is always equivalent to the one based on Level-k Thinking, in a similar manner as the variant based on Tâtonnement dynamics is always equivalent to the one based on lack of common knowledge. Unlike the latter, however, the new variants are not always able to capture the sought-after notion of GE attenuation. Consider, in particular, environments in which the GE effect offsets the PE effect, such as neoclassical

²The original development of our paper, which dates back to 2015, formalized the notion of GE attenuation only on the basis of the variants with Tâtonnement dynamics and lack of common knowledge. The additional variants that appear in the present draft have been included so as to elaborate on the relation between the present paper, our companion work (Angeletos and Lian, 2016a,c, 2017), and other recent work (Garcia-Schmidt and Woodford, 2015; Gabaix, 2016; Farhi and Werning, 2017).
settings in which agents compete for fixed resources; these environments are akin to games of strategic substitutability. In such environments, Cobweb dynamics and Level-k Thinking allow the relevant price or quantity conjectures to overshoot relative to the frictionless benchmark: every agent may expect the others to react more strongly to the shock than in that benchmark. Whenever this is the case, the relevant GE effects are amplified instead of being attenuated.

We view this overshooting to be a “pathological” prediction and show how it is avoided by the solution concept of García-Schmidt and Woodford (2015). This concept has the same flavor and the same underpinnings as Level-k Thinking. Yet, it entails a certain change that eliminates the aforementioned overshooting possibility. It therefore appears to be better suited for applied purposes.

Finally, consider the variant that builds on Gabaix (2016). This variant can naturally accommodate the sought-after notion of GE attenuation, but it is flexible enough to accommodate the exact opposite as well: it depends on the kind of bias one assumes in subjective beliefs, namely on whether the individual agent believes that the other agents respond less or more strongly than what they actually do. By contrast, the variants based on lack of common knowledge or reflective equilibrium predict that GE effects are necessarily attenuated.

**Dynamic Extension.** The aforementioned results help formalize the notion that GE adjustment is “weak”, but allow it to be as “instantaneous” as in the Arrow-Debreu paradigm. In an extension, we capture the complementary notion that GE adjustment “takes time” by allowing the relevant conjectures to adjust slowly from the pre-shock frictionless level to the post-shock one. In the variants that drop the REE concept, this requires the ad hoc assumption that the “depth of reasoning” increases with the time lag since the shock has hit the economy. In the variant with lack of common knowledge, instead, it obtains naturally from the property that beliefs converge to their frictionless counterparts as agents observe past market outcomes.

**Take-home Lessons.** The combination of our results yields GE attenuation as a robust prediction of either certain forms of bounded rationality or lack of common knowledge of the state of the economy. In this regard, the two methodological approaches appear to be close substitutes to each other.

Nevertheless, some of the considered forms of bounded rationality leave open the door to the opposite prediction. Furthermore, they all face certain conceptual and practical challenges. The most obvious one is the vulnerability to Lucas’s critique. Another one is the aforementioned question of why the depth of reasoning may, or may not, increase with time. For related reasons, these variants have difficulty in accommodating the notion that GE adjustment “takes time” in stationary environments with recurring shocks: doing so would have required that the agents be swallow thinkers vis-a-vis recent shocks and, at the same time, be deep thinkers vis-a-vis old shocks.

In our view, these observations tilt the balance in favor of the methodological approach that maintains rational expectations, removes common knowledge of the state of the economy, and relates GE attenuation to higher-order uncertainty. That said, since both informational and behavioral frictions seem empirically relevant, we find it reassuring for our purposes that the two kinds of friction can complement each other in the direction of attenuating GE effects.

**Applications.** Our framework is too abstract to permit a careful consideration of any particular application. We consider this to be a strength, because it allows us to deliver the key insights in a flexible manner and to connect to various strands of the literature. We study few applications in companion work, helping shed new light on the sources of the business cycle (Angeletos and Lian, 2016c), on monetary policy (Angeletos and Lian, 2016a), and on fiscal policy (Angeletos and Lian, 2017). The recent works by Farhi and Werning (2017) and Lovino and Sergeyev (2017), and a few earlier contributions such as Angeletos and La’O (2010), Venkateswaran (2014), and Schaal and Taschereau-Dumouchel (2015), can be seen as additional applications of the broader ideas we articulate in this paper.

**Layout.** Section 2 positions our paper in the literature. Sections 3 and 4 introduce the framework and the frictionless benchmark. Sections 5 and 6 explore the two leading variants, which build on Tâtonnement dynamics and on lack of common knowledge. Section 7 studies additional variants. Section 8 develops the notion that GE adjustment takes time. Section 9 discusses the key lessons and possible applications. Section 10 concludes.
2 Related Literature

Our paper builds heavily on the macroeconomic literature on incomplete information and especially on the influential contributions of Morris and Shin (1998, 2001, 2002, 2003) and Woodford (2003); see Angeletos and Lian (2016b) for a survey and additional references. We borrow from this literature the key insight that lack of common knowledge of the realized fundamentals impedes coordination and anchors higher-order beliefs. Our contribution includes (i) the translation of this insight in terms of the attenuation of GE effects in Walrasian settings and (ii) the building of a bridge between the aforementioned literature, the older tradition on Tâtonnement and Cobweb dynamics, and a recent literature that studies versions of the New-Keynesian framework that drop the REE concept. We also highlight that the relevant attenuation is robust to whether the environment features strategic complementarity or substitutability (or, relatedly, whether GE effects amplify or offset PE effects). Last but not least, we offer this attenuation as a potential remedy to the gap between the macro effects of interest and the kind of local elasticities estimated in, inter alia, Mian and Sufi (2012, 2014), Nakamura and Steinsson (2014) and Beraja, Hurst, and Ospina (2016).

By identifying predictions of the rational-expectations solution concept that are robust to the details of the information structure (which is probably unknown to the outside observer), we complement Bergemann and Morris (2013). That paper studies a class of games and focuses on the volatility and the dispersion of actions as the observables of interest. We instead study a Walrasian economy and focus on certain elasticities which are relevant vis-a-vis the aforementioned empirical literature, as well as for certain policy counterfactuals. We also develop a framework that is better suited for defining, and studying, the notion of weak or slow GE adjustment.

By modeling the economy as a collection of segmented markets and by letting, in our preferred variant, agents form rational expectations under dispersed information, we connect to Lucas (1972). Unlike that paper, however, we study a setting in which there are general-equilibrium spillovers across the different “islands”. This means that the economy is akin to a game, in which the behavior of each agent critically depends on her conjectures about the behavior of others. These conjectures—and the associated higher-order beliefs—play a central role in our analysis, as they do in the aforementioned theoretical literature, whereas they are irrelevant in Lucas (1972).

By allowing current markets to clear under possibly arbitrary conjectures of future prices, our partial-equilibrium analysis resembles the “temporary equilibrium” of Grandmont (1977); some subtle differences are explained in due course. By allowing the aforementioned conjectures to depart from their REE counterparts, we then connect to Guesnerie (1992), Evans and Ramey (1992, 1995), Evans and Honkapohja (2001), and the literature discussed in Woodford (2013). These works are concerned primarily with the question of whether the set of REE outcomes can be obtained as the limit of certain eductive or learning procedures. Our paper bypasses this question—by working with a framework in which the REE is the solution to a contraction mapping—and shifts the focus to a different theme.

By touching on the relation between micro and macro effects, our paper may appear to relate to the debate on whether micro rigidity implies macro rigidity (Caplin and Spulber, 1987; Caballero and Engel, 1999; Golosov and Lucas, 2007), or the debate on the elasticity of labor supply (Chetty et al., 2011, 2013; Keane and Rogerson, 2012). This is not the case, for neither of these debates is primarily concerned with GE effects. The former is about aggregation in settings with rich heterogeneity and non-linearity in PE effects. The latter is about the calibration of the key preference or others parameter that determines the PE response of labor supply to variation in wages.

Finally, it is worth clarifying the following two points. First, the mechanism we document in this paper affects the response of aggregate outcomes to aggregate shocks while holding constant the decision rules of the agents (or the supply and demand curves). Its observable implications are therefore different from those of adjustment costs,

7 Related is also the literature on rational inattention (Sims 2003; Mackowiak and Wiederholt 2009; Myatt and Wallace 2012; Pavan 2016), but only insofar as rational inattention ends up introducing higher-order uncertainty (i.e., uncertainty about the beliefs and the behavior of others) in environments with strategic or general-equilibrium interactions.

8 This literature studies models with fixed costs of adjustment. In such models, the relevant PE effect is zero for the firms that stay inside the region of inaction after the shock, but non-zero (and potentially very large) for the firms that are pushed outside that region.
inattention, sparsity, and other frictions that modify individual decision rules. Second, this mechanism can manifest either as under-reaction or as over-reaction to aggregate shocks relative to the frictionless benchmark. Which case obtains depends on whether the relevant GE effects amplify or offset the corresponding PE effects. Our work therefore provides a theory of GE attenuation, not a theory of under-reaction.

3 Framework

In this section, we introduce our baseline framework. We first spell out the micro-foundations of the framework, namely the market structure and the specification of preferences, technologies, and endowments. We next derive the associated demand and supply functions, which are the building blocks of our analysis. For reasons of tractability, we thereafter work the log-linearized demand and supply functions.

3.1 Marketplaces, Relocation, and Trading

Economic decisions take place over two periods, which we call “morning” and “afternoon”; these can be thought of as proxies for “present” and “future” in setting with more than two periods, such as the one we consider in Section 8. There is a double continuum of firms and households, each indexed by \( i \in [0, 1] \times [0, 1] \), and three goods. One good is storable and can be used for consumption and/or production in both periods. Possible examples include land and capital, or leisure as in Lagos and Wright (2005). We let this good serve as the numeraire. The remaining two goods, which we call the “morning good” and the “afternoon good”, are produced and consumed in the respective periods.

In each period, trade takes place in a continuum of segmented locations, which we call “marketplaces” and index by \( m \in [0, 1] \). Each marketplace operates two markets: one in the morning, where the morning good is traded with the numeraire; and another in the afternoon, where the afternoon good is traded with the numeraire. In each period, an agent can trade only in the marketplace she is currently in. As time passes, agents can move from one marketplace to another: after the morning markets have closed but before the afternoon ones have opened, each agent receives an idiosyncratic shock that determines whether she stays in her original marketplace or whether she gets relocated to a different marketplace. The probability of an agent’s staying in her original marketplace in the “afternoon” is \( \rho \in [0, 1] \) and that of relocating is \( 1 - \rho \). Conditional on reallocation, all other marketplaces are equally likely.

These assumptions are illustrated in Figure 1. The marketplaces are represented by the boxes in the figure. In the morning, an equal mass of agents is located to each of the marketplaces. After the morning market has cleared, relocation takes places: while a fraction \( \rho \in [0, 1] \) of the agents from each marketplace stay put, the remaining fraction
is randomly relocated to all other marketplaces. In the afternoon, each marketplace is therefore populated by two types of agents: a mass \( \rho \) of the agents that were originally located in that market; and a representative sample of the agents that where originally spread in the rest of the economy. As mentioned in the Introduction, these stark assumptions help capture two realistic features: that agents participate in a limited number of markets at any given point of time; and that agents nevertheless care about what’s going on in the rest of the economy because this affects their future trading opportunities and thereby also their current incentives.

The “fundamental”, meaning an exogenous variable that affects preferences, technologies and endowments, differs across agents. The initial distribution of agents is such that every marketplace receives equal masses of firms and households, but these masses are not representative samples of the entire population. This is illustrated in the figure by the fact that different boxes contain agents of different color. Note that, whether they relocate or not, agents maintain their original “color” (their preferences, technologies, and endowments). It follows that the average fundamental in a marketplace changes over time because, and only because, of the reshuffling in the composition of agents.

Without serious loss of generality, we finally assume that the original participants of any given marketplace share the same preferences, technologies and endowments. (In the figure, each box starts with agents that have exactly the same color, as opposed to having different shades of the same color.) This assumption lets us equate the idiosyncratic fundamental of any given agent with the average fundamental of the marketplace in which that agent participates during the morning. With this in mind, we henceforth let \( \theta_m \in \mathbb{R} \) denote the fundamental of the agents who participate in marketplace \( m \) during the morning. (Think of cross-sectional variation in \( \theta_m \) as the different colors in the figure.)

Remark. Marketplaces do not have to coincide with geographic regions. Accordingly, the assumption that agents move from one marketplace to another should not be interpreted as physical mobility. Instead, as in other works on decentralized trading, this assumption is only meant to capture the fact that every agent typically trades with different sets of other agents at different points of time. That said, when seeking to map the theory to the data, it seems plausible to assume that agents who are closer to each other in terms of geographic distance are more likely to participate in the same markets than agents that are further away from each other. We use this assumption in Appendix A—and only there—so as to relate our theoretical contribution to the empirical literature we mentioned in the introduction.

3.2 Technologies, Preferences, and Endowments

We now specify the details of the technology that is available to each firm and of the preferences and the endowments of each household. For our purposes, these details are relevant only insofar as they micro-found the demand and the supply functions we work with in the rest of the paper.

Consider a firm \( i \) that trades in marketplace \( m \) during the morning and in marketplace \( m' \) during the afternoon. Let \( q \) denote its net supply of the morning good, \( q_i^m \) its net supply of afternoon good, and \( q_i^n \) its net supply of the numeraire. Its technology is represented by a function \( \Gamma : \mathbb{R}^3 \to \mathbb{R} \) such that

\[
q_i^n = -\Gamma(q_i, q_i^m ; \theta_m)
\]

where \( \Gamma \) is strictly increasing and convex in \((q_i, q_i^m)\), satisfies \( \Gamma(0, 0; \theta_m) = 0 \), and is differentiable in all its arguments. In simple words, \( \Gamma(q_i, q_i^m; \theta_m) \) is the real cost of producing the pair \((q_i, q_i^m)\). The realized profit is thus given by

\[
\pi_i = p_m q_i + p_m^* q_i^m + q_i^n = p_m q_i + p_m^* q_i^m - \Gamma(q_i, q_i^m; \theta_m),
\]

where \( p_m \) is the price of morning good in market \( i \) and \( p_m^* \) is the price of afternoon goods in market \( m' \).

---

9E.g., Kiyotaki and Wright (1993), Lagos and Wright (2005), Angeletos and La’O (2013), and Golosov, Lorenzoni, and Tsyvinski (2014).
Consider next a household \( i \) that trades in marketplace \( m \) in the morning and marketplace \( m' \) in the afternoon. Her preferences are represented by the following utility function:

\[
U(c_i, c_i^*; \theta_m) + c_i^n,
\]

where \( U \) is twice differentiable, strictly increasing, and strictly concave, \( c_i \) denotes consumption of the morning goods, \( c_i^* \) denotes consumption of the afternoon goods, \( c_i^n \) denotes consumption of the numeraire, and \( \theta_m \) is the aforementioned exogenous fundamental.

The household’s endowment of the numeraire is allowed to depend on the local fundamental and is denoted by \( e(\theta_m) \). Without loss of generality, the endowments of the other two goods are set to zero. The budget constraint of the household is thus given by

\[
p_m c_i + p_m^* c_i^* + c_i^n = y_i \equiv e(\theta_m) + d_i,
\]

where \( d_i \) are the dividends the household receives from owning shares on the firms. Because preferences are quasi-linear in the numeraire, the answer to this question is irrelevant for our purposes because any variation in income is absorbed solely by the consumption of the numeraire. With this in mind, we let \( d_i = \int_{[0,1]} \pi_j d\xi \), which means that each household owns a fully diversified portfolio of all the firms in the economy.

Remark. We have allowed the preferences and the technology to be non-separable between the morning and the afternoon goods in order to introduce an interdependence between the morning and the afternoon outcomes. With separable preferences and technologies, the desired interdependence between the morning and the afternoon outcomes can be preserved by dropping the assumed quasi-linearity in the numeraire and by letting the agents trade bonds or money (i.e., to borrow and save) in addition to trading the real goods. See Angeletos and Lian (2016a,c) for concrete examples.

3.3 Demand, Supply, and Market Clearing

Throughout, we impose the following minimal requirements on what the agents know and do.

**Assumption 1.** Every agent knows her own \( \theta_i \), the prices at which she trades, the structure described in the previous two subsections, and the objects \((U, \Gamma, e, \rho)\). Furthermore, every household [respectively, firm] is individually rational in the sense that her chosen quantities maximize her utility [respectively, profits] given the aforementioned knowledge, the knowledge of the prices at which she trades, and her subjective belief of any unobserved variable.

**Assumption 2.** Subjective beliefs are the same within each marketplace (but can differ across marketplaces).

These assumptions are “minimal” in two complementary senses. First, they do not require that the agents know the aggregate shock \( \tilde{\theta} \), observe the prices in other marketplaces, or form rational expectations. Second, they suffice for obtaining the demand and the supply schedules in each marketplace under arbitrary subjective beliefs of the outcomes of other marketplaces.

To ease the analysis, we henceforth re-interpret all the variables as log-deviations from a symmetric steady state in which all marketplaces have the same fundamentals, and we work with the log-linearized demand and supply system. With potential abuse of notation, we also let \( \bar{c}_m \), \( q_m \), \( \bar{c}_m^* \), \( q_m^* \), etc., denote the average (log) consumption and the average (log) output in a marketplace \( m \). We next let \( \bar{c} \equiv \int \bar{c}_m dm \), \( \bar{q} \equiv \int \bar{q}_m dm \), etc., denote the economy-wide aggregates. We finally let \( \tilde{E}_m[p_m^*] \) denote the subjective—potentially irrational—belief that the typical agent in marketplace \( m \) holds about the price she is likely to face in the afternoon.\(^{10}\)

\(^{10}\)Keep in mind that, from the perspective of the individual agent, \( m' \) is a random variable that is revealed in the afternoon.
Lemma 1. There exist linear functions \( D, S, D^*, \) and \( S^* \) such that the following hold for every marketplace \( m \): the morning and afternoon demands are given by, respectively,

\[
c_m = D \left(p_m, \hat{E}_m[p_m^*], \theta_m\right)
\quad \text{and} \quad
c_m^* = \rho D^* \left(c_m, p_m^*, \theta_m\right) + (1 - \rho) D \left(\bar{c}_m, p_m^*, \theta\right),
\]

and the corresponding supplies are given by, respectively,

\[
q_m = S \left(p_m, \hat{E}_m[p_m^*], \theta_m\right)
\quad \text{and} \quad
q_m^* = \rho S^* \left(q_m, p_m^*, \theta_m\right) + (1 - \rho) S \left(\bar{q}_m, p_m^*, \theta\right).
\]

This result characterizes the demand-and-supply structure of the economy. Let us explain where it comes from. Thanks to the log-linearization, the morning demand of each household, and similarly the morning supply of each firm, can be expressed as a linear function of the local morning price, the local fundamental, and the local subjective belief of the afternoon prices. The left-hand sides of conditions (4) and (5) are self-explanatory. To understand the right-hand sides, note that the demand in any given afternoon market has two components: one reflecting the agents who were in this market from the morning; and another reflecting the agents who were relocated from other markets. The former have mass \( \rho \) and their demand is given by \( D^* \left(c_m, p_m^*, \theta_m\right) \); the latter have mass \( 1 - \rho \) and their average demand is given \( \int D^* \left(c_m', p_m^*, \theta_m\right) dm' = D^* \left(\bar{c}_m, p_m^*, \theta\right) \). The same logic applies on the supply side.

We next impose market clearing.

Assumption 3. Markets clear: \( c_m = q_m \) and \( c_m^* = q_m^* \), for all \( m \).

How much can we tell about the behavior of the economy on the basis of Assumptions 1, 2, and 3 alone? Unfortunately, they are not enough to predict how the economy responds to the aggregate shock. The reason is that these assumptions do not pin down the subjective beliefs that agents may hold in the morning about their trades in the afternoon. Nevertheless, these assumptions permit us to express the market-clearing outcomes of each marketplace as functions of the fundamentals and of these beliefs. We show this in the sequel.

3.4 The Mapping from Fundamentals and Subjective Beliefs to Observables

Consider the afternoon markets first. Using Lemma 1 and the fact that \( c_m = q_m \) for all \( m \) (by market clearing of the morning markets), the net afternoon demand in marketplace \( m \) can be expressed as follows:

\[
n_m^* = c_m^* - q_m^* = \rho N^* \left(q_m, p_m^*, \theta_m\right) + (1 - \rho) N^* \left(\bar{q}_m, p_m^*, \theta\right),
\]

where \( N^* \equiv D^* - S^* \). To guarantee the existence of a unique \( p_m^* \) that clears the afternoon market for every realization of the fundamentals and the morning quantities, we assume that \( U \) and \( F \) are such that \( N^* (\cdot, p^*, \cdot) \) is decreasing in \( p^* \). Finally, to characterize the market-clearing outcomes, we find it convenient to introduce two auxiliary variables: the average net demand, \( \bar{n}^* \equiv \int n_m dm \), and the average price,

\[
\bar{p}^* \equiv \int p_m dm.
\]

Aggregating condition (6) gives \( \bar{n}^* = N^* \left(\bar{q}, \bar{p}^*, \bar{\theta}\right) \), which in turn means that \( \bar{n}^* = 0 \) if and only if \( \bar{p}^* = P^* \left(\bar{q}, \bar{\theta}\right) \), where \( P^* \) is defined so that

\[
N^* (q, P^*(q, \theta), \theta) = 0,
\]

for all \( (q, \theta) \). Similarly, using (6), we have that, for every \( m \), \( n_m^* = 0 \) if and only if \( p_m^* = \rho P^* \left(q_m, \theta_m\right) + (1 - \rho) P^* \left(\bar{q}, \bar{\theta}\right) \). We therefore obtain the following characterization of the afternoon outcomes.
Lemma 2. There exist linear functions $Q^*$ and $P^*$ such that, for all realizations of the fundamentals and the morning quantities, the afternoon outcomes are given by

$$
\tilde{q}^* = Q^*(\tilde{q}, \tilde{\theta}), \quad \tilde{p}^* = P^*(\tilde{q}, \tilde{\theta}), \quad q_m = \rho Q^*(q_m, \theta_m) + (1 - \rho) \tilde{q}^* \forall m, \quad \text{and} \quad p_m^* = \rho P^*(q_m, \theta_m) + (1 - \rho) \tilde{p}^* \forall m.
$$

Consider next how the morning outcomes are determined. Using Lemma 1, the net demand in marketplace $m$ can be expressed as follows:

$$
n_m \equiv c_m - q_m = D(p_m, \hat{E}_m[p^*_m], \theta_m) - S(p_m, \hat{E}_m[p^*_m], \theta_m) = N(p_m, \hat{E}_m[p^*_m], \theta_m), \quad \text{where} \quad N \equiv D - S \text{ is the net (or excess) demand function.}
$$

Similarly to $N^*$, we assume that $U$ and $F$ are such that $N(p, \cdot, \cdot)$ is decreasing in $p$: all the relevant excess demand curves are downward slopping. It follows that, for every marketplace $m$ and every possible value of the pair $(\hat{E}_m[p^*_m], \theta_m)$, there exists a unique $p_m$ such that it clears the morning market. We denote this price and the corresponding market-clearing quantities by, respectively,

$$
p_m = \hat{P} \left( \hat{E}_m[p^*_m], \theta_m \right) \quad \text{and} \quad c_m = q_m = \hat{Q} \left( \hat{E}_m[p^*_m], \theta_m \right),
$$

where $\hat{P}$ and $\hat{Q}$ are linear functions (which can be deduced by the demand and supply functions, $D$ and $S$, or, equivalently, by the utility and the cost functions, $U$ and $\Gamma$).

Now note that, $\hat{E}_m[p^*_m]$, the subjective—potentially irrational—belief that the typical agent in marketplace $m$ holds about the price she is likely to face in the afternoon, has two components. Since this agent remains in marketplace $m$ in the afternoon with probability $\rho$ and is relocated to a random other marketplace with the remaining probability, we can express the aforementioned subjective probability as

$$
\hat{E}_m[p^*_m] = \rho \hat{E}_m[p^*_m] + (1 - \rho) \hat{E}_m[\tilde{p}^*].
$$

To make further progress, we now add the following assumption:

Assumption 4. Agents know that Assumptions 1, 2, and 3 are true.

This assumption guarantees that the agents know that afternoon prices satisfy $p_m^* = \rho P^* (q_m, \theta_m) + (1 - \rho) \tilde{p}^*$ in any marketplace. It also guarantees that, by observing the morning price, the agents can perfectly infer the value of $q_m$ in their own marketplace. From condition (10), we thus have have the subjective beliefs in marketplace $m$ satisfy the following restriction:

$$
\hat{E}_m[p^*_m] = \rho^2 P^* (q_m, \theta_m) + (1 - \rho^2) \hat{E}_m[\tilde{p}^*]. \quad \text{(11)}
$$

Let $\hat{\alpha} \equiv \frac{\partial \hat{E}_m[\tilde{p}^*]}{\partial \tilde{\theta}}$. Provided that $\rho^2 \hat{\alpha} \neq 1$, which we henceforth assume, we can combine the above expression with condition 9 and solve for $q_m$ as a function of $\theta_m$ and $\hat{E}_m[\tilde{p}^*]$, and can then obtain the corresponding aggregate as a function of $\theta$ and of the average expectation of $\tilde{p}^*$: $\int \hat{E}_m[\tilde{p}^*] \, dm$. We thus obtain the following characterization of the morning outcomes.

Lemma 3. There exist linear functions $Q$ and $P$ such that, for all $m$,

$$
q_m = Q \left( \hat{E}_m[\tilde{p}^*], \theta_m \right) \quad \text{and} \quad p_m = P \left( \hat{E}_m[\tilde{p}^*], \theta_m \right).
$$

Furthermore, this fact, the fact stated in Lemma 2, and the functions $(Q, P, Q^*, P^*)$ are known to every agent (but are not necessarily common knowledge to them).
By expressing the market-clearing outcomes in the morning as functions of arbitrary subjective beliefs of the afternoon prices, we touch on the literature on “temporary equilibrium” (Grandmont, 1977). The twist is that, by introducing segmented marketplaces and imposing Assumption 4, we have equated the “temporary equilibrium” of the entire economy with the “partial equilibrium” of each marketplace in isolation.

To sum up, Lemmas 2 and 3 have shown how the morning outcomes can be expressed as functions of the fundamentals and of certain conjectures and how the afternoon outcomes can in turn be expressed as functions of the fundamentals and the morning outcomes. To reach this point, we have only relied on Assumptions 1-4. These assumptions are noticeably weaker than those often made in applied research, because they do not impose common knowledge of either the underlying shocks or the rationality and the decision rules of others. As a result, these assumptions leave free the conjectures that the typical agent in the morning can hold about the concurrent behavior of agents in other marketplaces and, by the same token, about the prices she may herself face in the afternoon.

To form predictions about how the relevant economic outcomes—prices and quantities—respond to an exogenous shock, we need to specify how the aforementioned conjectures are formed and adjust to the shock. We complete this task in the next a few sections of the paper, under different assumptions about the solution concept and the information that is available to the agents. We close the present section by specifying the shock under consideration.

3.5 The Exogenous Shock

Denote with \( \bar{\theta} = \int \theta_m dm \) the aggregate, or average, fundamental. Throughout, we let \( \bar{\theta} \) be a single-dimensional variable, \( \bar{\theta} \in \mathbb{R} \), and focus on a once-and-for-all change in it, from some initial level, \( \bar{\theta} = \bar{\theta}_{old} \), to some new level, \( \bar{\theta} = \bar{\theta}_{new} \neq \bar{\theta}_{old} \). We treat the initial level, \( \bar{\theta}_{old} \), as a fixed parameter (and hence as a commonly known object) and the change, \( \Delta \bar{\theta} = \bar{\theta}_{new} - \bar{\theta}_{old} \), as a random variable drawn from a Normal distribution with mean 0 and variance \( \sigma_{\theta}^2 \).

We next specify the corresponding changes in the “local” fundamentals as follows:

\[
\Delta \theta_m = \delta_m \Delta \bar{\theta} + z_m \tag{12}
\]

where \( \Delta \theta_m \) is the change in the fundamental of any agent who is located in marketplace \( m \) in the morning, \( \delta_m \) is a fixed parameter that captures the exposure of \( m \) to the aggregate shock, with \( \int \delta_m dm = 1 \), and \( z_m \) is a purely idiosyncratic shock. The latter is independent of \( \Delta \bar{\theta} \), is drawn from a Normal distribution whose mean is zero and whose p.d.f. is henceforth denoted by \( \varphi \), and is such that \( \int z_m dm = \int z \varphi(z)dz = 0 \) for all realizations of uncertainty.

The question of interest is how the observables of the economy (quantities or prices) respond to the aforementioned shock. This can be split into two parts. First, how does the shock shift demand and supply in each marketplace for given conjectures of the outcomes in other marketplaces? Second, how does it shift the conjectures themselves? The answer to the first part can readily be obtained from Lemmas 3 and 2. The answer to the second part requires additional assumptions, namely a solution concept and a specification of the information that the agents have about markets they do not currently participate in.

4 The Frictionless Benchmark

Our benchmark is defined by imposing the Rational Expectations Equilibrium (REE) concept along with the assumption that, at any given period, the cross-sectional profile of the fundamentals is common knowledge. More specifically, we assume that all agents share the same information in the morning and this information contains the entire profile of \( (\theta_m, p_m)_{m \in [0,1]} \) in the economy; all agents know this fact; all agents know that all agents know this fact; and so on. Admittedly, this is a strong assumption; but it is the standard one.
Remark 1. The assumption that agents share the same information in the morning does alone not pin down their subjective beliefs about the afternoon prices. In combination with the REE concept, however, it guarantees that all agents share the same subjective beliefs and that these beliefs indeed coincide with the objective, rational, expectation of the afternoon prices. In what follows, we prove this property and characterize the economy’s outcomes.

Remark 2. In our setting, the rational expectation of the afternoon prices happen to coincide with the actual realizations of these prices, due to our simplifying assumption that there are no shocks to fundamentals between the morning and the afternoon. This means that Rational-Expectations Equilibrium (REE) coincides with Perfect Foresight Equilibrium (PFE). However, as explained below, our characterization of the relevant expectations and of the associated morning outcomes is robust to dropping the aforementioned assumption.

4.1 From Subjective Conjectures to Rational Expectations

Having imposed rational expectations, we can replace $E_m [\tilde{p}^*]$ in Lemma 3 with $E [\tilde{p}^*]$, where $E$ denotes the rational expectation operator (conditional on the morning information). We thus have that the aggregate quantity in the morning satisfies $\tilde{q} = Q (E [\tilde{p}^*], \theta)$. From Lemma 2, on the other hand, we have that the realized average price in the afternoon is given by $\tilde{p}^* = P^*(\tilde{q}, \tilde{\theta})$. Combining these two fact imposes the following restriction between the realized average price in the afternoon and the rational expectation of it in the morning:

$$\tilde{p}^* = T (E [\tilde{p}^*], \tilde{\theta}),$$

where $T (p^*, \theta) \equiv P^* (Q (p^*, \theta), \theta)$. Taking expectations on both sides and using the assumption that $\tilde{\theta}$ is known and the fact that $E [E [\tilde{p}^*]] = E [\tilde{p}^*]$, we infer that the rational expectation solves the following fixed-point relation:

$$E [\tilde{p}^*] = T (E [\tilde{p}^*], \tilde{\theta}).$$

Furthermore, the REE concept imposes that all the above facts are themselves commonly known to all agents. It follows that both we, the outside observers, and the agents inside the model know that $\tilde{p}^* = E [\tilde{p}^*]$ and that $E [\tilde{p}^*]$ is itself pinned down by the fixed points of the mapping $T$.

As noted earlier, the exact coincidence between $p^*$ and $E[\tilde{p}^*]$ is due to the assumption that no innovation in the aggregate fundamentals is possible between the morning and the afternoon. If we were to relax this assumption, the morning quantities would still satisfy $\tilde{q} = Q (E [\tilde{p}^*], \theta)$, but now the afternoon prices would be given by $\tilde{p}^* = P^*(q, \tilde{\theta}) + \epsilon$, where $\epsilon$ is a term that captures the effect of the realized innovation. As a result, condition (13) would now have to be replaced by $\tilde{p}^* = T (E [\tilde{p}^*], \theta) + \epsilon$. Nevertheless, because $\epsilon$ is unpredictable in the morning, condition (14) would still hold. We conclude that, even when the realized $\tilde{p}^*$ varies around $E[\tilde{p}^*]$ due to innovations in fundamentals, $T$ is the mapping whose fixed points pin down the values of $E[\tilde{p}^*]$ that are consistent with REE.

Note that the slope of $T (p^*, \theta)$ with respect to $p^*$ is given by

$$\alpha \equiv \frac{\partial T}{\partial p^*} = \frac{1 - \rho^2}{1 - \alpha \rho^2},$$

where $\alpha \equiv \frac{\partial T}{\partial q} \frac{\partial q}{\partial p^*}$. To guarantee that $T$ is contraction mapping for every $\rho$, we make the following assumption.

Assumption 5. $\alpha \in (-1, 1)$.

---

11 By an “innovation” we mean a change that is unpredictable in the morning. Predictable changes (sometimes referred to as “news shocks”) are already nested, because we have not restricted how $\theta$ enters preferences and technology.

12 This assumption is, not only necessary and sufficient for $T$ to be a contraction mapping regardless of the value of $\rho$, but also sufficient for the property $\rho^2 \alpha \neq 1$, which was used in the construction of $T$ in the first place.
Given this assumption, we can solve (14) for $\mathbb{E} [\bar{p}^*]$ as a function of $\hat{\theta}$ — and so can the agents inside the model. We thus reach at the following result, which completes the equilibrium characterization of our benchmark.

**Proposition 1.** The equilibrium exists, is unique, and is such the following is true:

(i) The rational expectation of $\bar{p}^*$ is given by

$$\mathbb{E}[\bar{p}^*] = \mathcal{P}(\hat{\theta})$$

where the function $\mathcal{P}$ is defined by the fixed point of $\mathcal{T}$.

(ii) The equilibrium prices and quantities are given by Lemmas 2 and 3, replacing $\hat{E}_m [\bar{p}^*]$, for every $m$, with $\mathcal{P}(\hat{\theta})$.

**Remark.** In the preceding analysis, we have assumed that agents have common knowledge of $(\theta_m, p_m)_{m\in[0,1]}$, the entire cross-sectional profile of the fundamentals and the prices. This assumption is consistent with those often made in applied research, but is stronger than what is strictly needed in the present setting for the frictionless outcomes to obtain: the same outcomes can be replicated under the weaker assumption that agents have common knowledge of merely $\hat{\theta}$ and $\bar{p}$. Note, however, that, in settings with richer matching/trading structures, common knowledge of the average fundamental and/or the average price is generally not enough for replicating the frictionless outcomes.

### 4.2 Micro vs Macro, and PE vs GE

We are now ready to characterize how the morning outcomes respond to aggregate shocks. We focus on the morning outcomes because we think of them as better proxies for the kind of outcomes that may be observable to an “econometrician” in the context of applications. This is because the “afternoon” in our model proxies the role of all the relevant future market interactions, which may have not even be realized by the time the econometrician makes her measurements. To simplify the exposition, we also focus on quantities; similar results apply for prices as well.

Combining the two parts of Proposition 1, we have that the realized quantities at the local and aggregate level are given by, respectively,

$$q_m = Q(\mathcal{P}(\hat{\theta}), \theta_m) \quad \text{and} \quad \bar{q} = Q(\mathcal{P}(\hat{\theta}), \bar{\theta}).$$

Letting $\Delta$ denote the change in a variable relative to its pre-shock value, we have the following result.

**Proposition 2.** There exist scalars $\epsilon_{\text{micro}}$ and $\epsilon_{\text{Macro}}$ such that, for all realizations of the underlying aggregate and idiosyncratic shocks, the corresponding changes in the equilibrium quantities are given by

$$\Delta q_m = \Delta \bar{q} + \epsilon_{\text{micro}} (\Delta \bar{\theta}_m - \Delta \bar{\theta}) \quad \text{and} \quad \Delta \bar{q} = \epsilon_{\text{Macro}} \Delta \bar{\theta}.$$

The scalar $\epsilon_{\text{micro}}$ measures the elasticity of local activity to a local shock or, equivalently, to the interaction of $\delta_m$ with the aggregate shock. As explained in Appendix A, this object is therefore closely related the kind of local elasticities estimated in a growing empirical literature that exploits the cross-sectional heterogeneity in the exposure to aggregate shocks (e.g. Mian and Sufi 2014). We henceforth refer to $\epsilon_{\text{micro}}$ as the “micro elasticity”.

The scalar $\epsilon_{\text{Macro}}$, on the other hand, measures the total effect of the aggregate shock on aggregate activity. We henceforth refer to $\epsilon_{\text{Macro}}$ as the “macro elasticity”. This differs from $\epsilon_{\text{micro}}$ because, and only because, of the GE spillover across the different marketplaces. To see this, compare the following two scenarios. In the first, we consider an aggregate shock; let the agents understand that the shock hits all marketplaces at once and that, as result, $\bar{p}^*$ will adjust accordingly; and measure the resulting response in $\bar{q}$. In the second, we consider the same aggregate shock but fix the subjective beliefs that the agents hold about the activity in other marketplace and about $\bar{p}^*$ to their pre-shock values. The first scenario identifies $\epsilon_{\text{Macro}}$. The second scenario isolates the PE effect of the aggregate shock: it captures the aggregate response that obtains when we hit all markets at once with the aggregate shock and nevertheless have
each market respond as if the shock was specific to that market or, equivalently, as if the agents expected \( p^* \) to stay constant. Clearly, this PE effect coincides with \( \epsilon^{\text{micro}} \). It follows that the gap between \( \epsilon^{\text{Macro}} \) and \( \epsilon^{\text{micro}} \) captures the GE effect the aggregate shock, that is, the additional effect that obtains once we, and the agents inside the model, take into account that \( p^* \) itself adjusts in response to the aggregate shock so as to clear the afternoon markets.

We summarize these points in the following corollary.

**Corollary 1.** The macro elasticity can be decomposed to a PE and a GE component: \( \epsilon^{\text{Macro}} = \text{PE} + \text{GE} \), where

\[
\text{PE} \equiv \int \left( \frac{\partial Q}{\partial m} \delta_m \right) dm \quad \text{and} \quad \text{GE} \equiv \frac{\partial Q}{\partial p} \frac{\partial p}{\partial m}.
\]

The PE effect is measured by the micro elasticity: \( \epsilon^{\text{micro}} = \text{PE} \). The gap between the two elasticities therefore measures the GE effect of the shock.\(^{13}\)

The aforementioned gap can be either negative or positive. Without loss of generality, let \( \epsilon^{\text{micro}} > 0 \). The case in which \( \epsilon^{\text{Macro}} > \epsilon^{\text{micro}} \) captures settings in which the GE effect works in the same direction as the PE effect, acting as an amplification mechanism. The alternative case, \( \epsilon^{\text{Macro}} < \epsilon^{\text{micro}} \), captures settings in which the GE effect works in the opposite direction than the PE effect. We illustrate these two scenarios in the two panels of Figure 2, using the example of a demand shock. In both panels, the PE effect of the shock is represented by the movement from point \( X \) to point \( Y \). Because we are considering a demand shock, this entails a shift in the demand curve holding constant the supply curve. The GE effect, on the other hand, is represented by the movement from point \( Y \) to point \( Z \). This entails a shift in the supply curve, as well as a further shift in the demand curve, because of the endogenous adjustment in \( p^* \). In the left panel, this adjustment amplifies the PE effect; in the right panel, it mitigates it.

![Figure 2: PE and GE effects](image)

In what follows, we do not take a stand on which of these two cases applies: the GE effect may either amplify or offset the PE effect. To make the analysis interesting, we only impose the following.

**Assumption 6.** The GE effect is non-zero: \( \frac{\partial Q}{\partial p} \frac{\partial p}{\partial m} \neq 0 \).

We conclude this discussion with the following elementary observation. In the frictionless benchmark, the aggregate shock causes the economy to jump from point \( X \) to point \( Z \), regardless of where \( Z \) is located relative to \( Y \). This underscores that the decomposition between PE and GE effect is irrelevant for the observables of the economy at the aggregate level: all that matters is the total macroeconomic effect. By contrast, the modifications we study in the rest of the paper Sections 5–7 will try to make sense of why this decomposition may be relevant and why the GE

\(^{13}\)A few clarifications about terminology. First, the overall general-equilibrium response of \( q \) to the aggregate shock is given by the entire \( \epsilon^{\text{Macro}} \), what we henceforth call GE effect is the component due to the adjustment of \( p^* \), that is, the effect that occurs beyond the PE effect. Second, what we call PE effect in this paper is sometimes referred to as local GE effect in applied work. Finally, whereas we use the term “effect” to refer to the marginal effect of a shock, in applied work the same term is often used to refer to the marginal effect times the size of the shock.
adjustment may be “partial” in the sense that economy moves to a point in the middle of the segment between \( Y \) and \( Z \) rather than all the way to \( Z \).

**Remark.** In dynamic settings, the analogues of \( \epsilon^{\text{micro}} \) and \( \epsilon^{\text{Macro}} \) are the impulse response functions of, respectively, local and aggregate outcomes to, respectively, local and aggregate shocks. What we are interested in is the GE gap between the two, not the technological or other factors that may drive the precise shape of these responses.

### 4.3 Connection to Arrow-Debreu and Additional Clarifications

We now show that the outcomes of our frictionless benchmark coincide with those of an appropriate Arrow-Debreu variant, which lets all markets operate at once and recasts the random matching as idiosyncratic technology and preference shocks.\(^{14}\) This helps clarify some basic ideas and refine the context of our contribution.

In the considered variant, there is neither sequential trading nor segmented marketplaces. Instead, there is a single centralized market, which operates only once, but allows agents to trade over a sufficiently rich set of commodities. This set includes a numeraire and multiple varieties of “morning” and “afternoon” goods. These varieties are indexed by \( (m, m') \in [0, 1]^2 \). Finally, there are a double continuum of households and a double continuum of firms, each indexed by \( i = (i_1, i_2) \in [0, 1]^2 \).

Every household likes to consume a single variety of the morning good and a single variety of the afternoon good. She knows a priori the variety of the morning good she likes, but faces idiosyncratic uncertainty about the likable variety of the afternoon good contingent on the realization of her idiosyncratic uncertainty, her budget can be expressed as follows:

\[
U_i = \rho \left[ U(c_i, e^*_{i,m}, e_{i,m}^n) + c_{i,m}^n \right] + (1 - \rho) \int \left[ U(c_i, e^*_{i,m'}, e_{i,m'}^n) + c_{i,m'}^n \right] dm',
\]

where \( c_{i,m'}^* \) and \( c_{i,m'}^n \) denote the consumption of the afternoon goods and the numeraire. As standard in the Arrow-Debreu paradigm, the household’s uncertainty is subsumed in her preferences: it is as if the household faces no uncertainty, likes all the varieties of the afternoon good, and happens to have the preferences defined above. By the same token, because the Arrow-Debreu structure permits each agent to make her purchase of each variety of the afternoon good contingent on the realization of her idiosyncratic uncertainty, her budget can be expressed as follows:

\[
p_m c_i + \rho \left( p^*_m c^*_{i,m} + c^{'*}_{i,m} \right) + (1 - \rho) \int \left( p^*_m c^*_{i,m'} + c^{'*}_{i,m'} \right) dm' = y_i,
\]

where \( y_i = e_i(\theta) + \Pi \) and where \( \Pi \) are the total profits in the economy.

We make similar assumptions on the production side. Each firm can produce a single variety of the morning good and a single variety of the afternoon good; knows a priori the morning variety; and faces idiosyncratic uncertainty about the afternoon variety. Consider a firm \( i \) that produces variety \( m \) of the morning good. It produces variety \( m' = m \) of the afternoon good with probability \( \rho \in [0, 1] \); and with the remaining probability, the variety she can produce is drawn from uniform distribution over \([0, 1]\). It follows that the firm’s expected profit is given by

\[
p_m q_i + \rho \left\{ p^*_m q^*_i, m - K(q_i, q^*_i, m) \right\} + (1 - \rho) \left\{ \int p^*_m q^*_i, m' - K(q_i, q^*_i, m') \right\} dm',
\]

where \( q_{i,m'}^* \) and \( c_{i,m'}^n \) is firm \( i \)'s production of afternoon goods and numeraire if she likes variety \( m' \) in the afternoon.

It is straightforward to show that the variant described above gives rise to the same equilibrium prices and quantities

\(^{14}\)To set up the present variant, we momentarily revert to the interpretation of the variables prior to log-linearization.
as our frictionless benchmark. The only difference is the following: what used to be forward-looking price conjectures in that benchmark have been recast as actual prices in the present variant. By the same token, what was a dynamic GE effect in the former has been recast as a static GE effect in the latter.

### 4.4 Remarks

**Remark 1.** If one takes the view that any given agent can engage in a single market interaction at any given instant of time, then all GE effects are of a dynamic nature and are tied to expectations. This perspective explains our choice to equate the GE effects that operate across marketplaces to a certain kind of expectations. But as we have just illustrated, these expectations need not play an essential role under the frictionless benchmark: in that benchmark, it is as if all interactions happen at once, in which case expectations are inactive and all GE effects are static.

**Remark 2.** Our frictionless benchmark is akin to assuming that all agents can get together in the same room and can perfectly and instantaneously coordinate both their current and their future reaction to the underlying aggregate shock. Here, this point was formalized by showing that our benchmark attains the same outcomes as an Arrow-Debreu variant that leaves essentially no room for either dynamics or expectations. Later on, we will further corroborate the same idea by showing that our frictionless benchmark is akin to a static, complete-information, game in which players face no uncertainty about one another’s actions.

**Remark 3.** The standard modeling practice often departs from the Arrow-Debreu framework by allowing for incomplete markets, monopoly power, and the like. Yet, by imposing the REE concept along with public information about aggregate shocks, standard practice preserves the aforementioned kind of frictionless coordination in the adjustment of beliefs, behavior, and prices to aggregate shocks. By contrast, what we are after in this paper is precisely the introduction of a certain friction in this kind of adjustment—a friction that can be interpreted as attenuating the relevant GE effects.

**Remark 4.** For applied purposes, it is often appealing to abstract from the fact that most real-world trading is sequential and, instead, represent the economy with a static model. In such models, one can still tie GE effects to expectations by letting each household or firm have multiple selves, each of which engages in one market interaction and must forecast the choices of other shelves. Think of this as a “big family” or a “team problem” : every member of the family/team makes a choice that contributes towards a common goal, without necessarily having knowledge of the choices of other members.

**Remark 5.** When an analyst uses a model to form predictions about the response of economic outcomes to preference and technology shocks or to policy changes, she is of course aware that these predictions are sensitive to the assumptions made. This sensitivity is not terribly bothering if the predictions are “unbiased” in the sense that a perturbation of the underlying assumptions can change the predictions in either direction. As an example, consider the predictions made by assuming a logarithmic utility and a Cobb-Douglas production function; these predictions are in the “middle” of the set of the predictions that obtain with a relaxed, CES, specification for preferences and technologies. Unfortunately, this is not the case with the assumption of common knowledge: we will show that the predictions that are made on the basis of this assumption are “biased” in the sense that they necessarily overstate the relevant GE effect relative to the alternative of allowing for imperfect common knowledge.

### 5 Cognitive Tâtonnement

In the frictionless benchmark, the agents in each marketplace form rational expectations about the outcomes in other marketplaces and, equivalently, about \( \bar{p}^* \). Our first variant allows the agents to make irrational conjectures about \( \bar{p}^* \).

---

15See Angeletos and Lian (2016c) for an application along these lines.
These conjectures, however, are not entirely arbitrary. Instead, they are the product of an algorithm that resembles Tâtonnement dynamics. Relative to the traditional version of this concept, the twist here is that there are no actual dynamics; instead, we are merely replacing rational expectations with another instantaneous cognitive process, which happens to be defined by the solution to a certain differential equation as opposed to the REE fixed point.

Let us elaborate. The assumed algorithm consists of multiple rounds of making an initial conjecture about $\hat{p}^*$, calculating the implied imbalance in the market for afternoon goods, and subsequently updating the original conjecture in the direction that helps reduce the imbalance. We index the rounds by calculating the implied imbalance in the market for afternoon goods, and subsequently updating the original conjecture.

Part (i) is equivalent to imposing Assumptions 1–4 along with the additional restriction that the subjective belief of $\hat{p}^*$ is the same across all marketplaces. Part (ii) then specifies this belief as the product of the following iterative procedure. An initial conjecture is formed at round $t = 0$ by letting $\hat{p}^*(0)$ coincide with $\bar{p}_{old}$, the pre-shock equilibrium price. Using this conjecture, the agent computes the implied aggregate demand and supply for afternoon goods and subsequently adjusts her conjecture as follows: if the excess demand is positive, the conjecture is adjusted upwards; if, instead, the excess demand is negative, the conjecture is adjusted downwards. The same updating procedure is applied at all $t \in (0, T)$. At $t = T$, the updating terminates, generating the final conjecture, $\hat{p}^* = \hat{P}^*(T)$, upon which actual behavior is based.

In Section 8, we develop a variant model that allows the relevant economic decisions to be repeated over many periods. In that variant, every period other than the very first one serves as the “afternoon” vis-a-vis the previous period. By the same token, the outcomes in any given period depend on a price conjecture about the next period. This permit us to map the passage of calendar time to an increase in the parameter $T$ that shows up in the above definition and, in this sense, give a real-time interpretation to the cognitive procedure. For the present purposes, however, we opt to interpret a higher $T$ as a higher “depth of reasoning”.

In the rest of this section, we characterize the price conjecture and the outcomes that obtain when the REE concept is replaced with the solution concept proposed in Definition 1. We then show how this attenuates the GE adjustment relative to our frictionless benchmark, thus also helping reduce the gap between the micro and the macro elasticities.

Consider first the price conjecture $\hat{p}^*$. Under Assumption 5, which means that $T$ is contraction mapping, the assumption that $N^*$ is decreasing in $p^*$ guarantees that $\mathcal{N}$ is also decreasing in $p^*$. It follows that the solution to the

---

17The function $\mathcal{P}$ is the same as that obtained in condition 16.
18This hints at a connection to the concept of Level-k Thinking in games; we explore this connection is Section 7.
19Strictly speaking, the weaker assumption $\alpha < 1$ suffices for all the results of this section.
Tâtonnement ODE is continuous in $T$ and converges monotonically to the value of $p^*$ that solves $N(p^*, \tilde{\theta}_{new}) = 0$. And because this value coincides with the post-shock frictionless equilibrium price, the following is true.

**Lemma 4.** There exists a continuous and strictly increasing function $w : \mathbb{R}_+ \rightarrow [0, 1]$, with $w(0) = 0$ and $\lim_{T \to \infty} w(T) = 1$, such that, for any $T$ and any $\Delta \tilde{\theta}$, the conjecture $\hat{p}^*$ satisfies

$$\hat{p}^* = p^*_{old} + w(T)(\tilde{p}^*_{new} - \tilde{p}^*_{old}),$$

(19)

where $p^*_{old} \equiv P(\tilde{\theta}_{old}), \tilde{p}^*_{new} \equiv P(\tilde{\theta}_{new})$, and $\tilde{\theta}_{new} \equiv \tilde{\theta}_{old} + \Delta \tilde{\theta}$.

Because $w(T)$ is bounded between 0 and 1, we have that the conjecture $\hat{p}^*$ adjusts less to the underlying shock than the rational expectation of $p^*$ does in the frictionless benchmark. It is in this sense that the GE adjustment is attenuated. Furthermore, by varying $T$, we can let the conjecture $\hat{p}^*$ span the entire interval between $\tilde{p}^*_{old}$ and $\tilde{p}^*_{new}$, that is, we can span the entire adjustment that happens in $\hat{p}^*$ in the REE benchmark. Furthermore, the higher $T$ is, the closer the conjecture is to the post-equilibrium price. Given the proposed interpretation of $T$ as “depth of reasoning”, we have that deeper reasoning maps to a smaller error relative to the REE benchmark.

The property that the Tâtonnement conjecture $\hat{p}^*$ adjust less to the underlying shock than the frictionless counterpart does need not be surprising. It is, however, instrumental to the broader theme of our paper. In Section 7, we discuss why this property may not be shared by few other plausible kinds of bounded rationality. In the next section, on the other hand, we show how essentially the same property can be rationalized in a variant that preserves the REE concept but removes common knowledge of the shock. Together with the results of Section 8, this facilitates the interpretation of our preferred approach—lack of common knowledge—as a rationalization of the older idea that GE adjustment may be “weak” in the short run.

It is also worth noting the following two points. First, the result depends on the excess demand for the afternoon good being decreasing in its price. Without this property, the distance between the conjecture $\hat{p}^*$ and its REE counterpart would actually increase without bound as $T$ increases. In the literature, this issue is known as “Tâtonnement stability” and is tied to the gross substitutability of goods. Second, the result depends on treating the rounds of the Tâtonnement process as a continuous rather than a discrete variable in the following regard. Under the adopted specification, the following properties are true regardless of the precise slope of $N$: (i) by varying $T$ in $\mathbb{R}_+$, we can let $\hat{p}^*$ span the entire interval between $\tilde{p}^*_{old}$ and $\tilde{p}^*_{new}$; (ii) $\hat{p}^*$ can never fall outside this interval; (iii) $\hat{p}^*$ converges monotonically to $\tilde{p}^*_{new}$ as $T \to \infty$. If instead we had let $t$ be discrete, these properties would not necessarily hold: we would have to restrict the slope of $N$ and/or modify the speed of the Tâtonnement process.

Consider now the observable outcomes that obtain on the basis of the conjecture characterized in Lemma 4. By Lemma 3, we have that, for every $m$,

$$q_m = Q(\hat{p}^*, \theta_m).$$

(20)

That is, the morning quantities are determined in the same fashion as in our frictionless REE benchmark, except for the fact that the rational expectation $E[\hat{p}^*]$ has been replaced with the Tâtonnement-based conjecture $\hat{p}^*$. By direct implication, the aggregate output of morning goods can be expressed as $\bar{q} \equiv \int q_m dm = Q(\hat{p}^*, \tilde{\theta})$; and because of the linearity of $Q$, the change in $\bar{q}$ triggered by the aggregate shock can be expressed as

$$\Delta \bar{q} = \frac{\partial Q}{\partial \tilde{\theta}} \Delta \tilde{\theta} + \frac{\partial Q}{\partial p^*}(\hat{p}^* - \tilde{p}^*_{old})$$

(21)

---

20Recall our earlier remark about the possibility of allowing for innovations in the fundamentals to occur between the morning and the afternoon. In such an extension, $P(\theta)$ gives, not the realized $p^*$, but rather its rational expectation in the morning. With this in mind, it is best to interpret $\tilde{p}^*_{old}$ and $\tilde{p}^*_{new}$ as the frictionless values of the rational expectation of $p^*$.

22By this we mean letting $P^*(t + 1) - P^*(t) = b(t)\mathcal{N}(P^*(t), \theta_{new})$ for an appropriately chosen $b : \mathbb{N} \to \mathbb{R}_+$. 
Using the above property together with Lemma 4, we arrive at the following result.

**Proposition 3** (Tâtonnement). For every $T$, there exists a scalar $\epsilon_{T\Delta}(T)$ such that, for any realization $\Delta \hat{\theta}$ of the aggregate shock, the corresponding change in $\delta$ that obtains along the Tâtonnement($T$) solution is given by

$$\Delta \delta = \epsilon_{T\Delta}(T) \Delta \hat{\theta}.$$  

Furthermore,

$$\epsilon_{T\Delta}(T) = \epsilon^{\text{micro}} + w(T) (\epsilon^{\text{Macro}} - \epsilon^{\text{micro}}),$$  

(22)

where $\epsilon^{\text{micro}}$ and $\epsilon^{\text{Macro}}$ are the same objects as in Section 4 and where $w$ is the same function as the one in Lemma 4 (hence, $w$ is continuous and strictly increasing in $T$, with $w(0) = 0$ and $w(\infty) \equiv \lim_{T \to \infty} w(T) = 1$).

In short, $\epsilon_{T\Delta}(T)$ identifies the macro elasticity of the Tâtonnement economy in which the depth of reasoning is $T$. This elasticity is arbitrarily close to the underlying micro elasticity when $T$ is low enough, but gets closer and closer to the macro elasticity of the frictionless REE benchmark as $T$ increases. This reflects the fact that, by design, the Tâtonnement process helps arrest the GE adjustment that is present in that benchmark. Formally, using Lemma 4, the GE effect of the modified economy can itself be expressed as

$$\text{GE}_{T\Delta}(T) = \frac{\partial Q}{\partial p^*} \frac{\hat{\beta}^* - \hat{\beta}_{\text{add}}}{\Delta \hat{\theta}} = w(T) \text{GE},$$

where $\text{GE} \equiv \frac{\partial Q}{\partial p^*} \frac{\partial p^*}{\partial \theta^*}$ ($= \epsilon^{\text{Macro}} - \epsilon^{\text{micro}}$) is the GE effect of the frictionless benchmark and where $w(T)$ is the aforementioned function. Accordingly, the fact that $w(T) \in (0, 1)$ for all $T > 0$ formalizes the notion that GE adjustment is “incomplete”, or that it is “weakened” by the considered relaxation of the solution concept; and the fact that $w(T)$ increases with $T$ can be interpreted as the property that a larger GE adjustment requires “deeper reasoning”.  

We illustrate these points with the help of Figure 2. In the frictionless benchmark, the effect of the aggregate shock is represented by the shift from point X to point Z. Furthermore, this shift can be decomposed to a PE adjustment, captured by the shift from X to Y, and a GE adjustment, captured by the shift from Y to Z. With the considered modification, the PE adjustment remains the same, but the GE adjustment is cut short: the economy moves to an intermediate point along the segment between Y and Z. The smaller T is, the closer to Y the economy gets stuck.

**Remark.** By treating the Tâtonnement dynamics as a cognitive process that takes place within a fixed moment in time, we have formalized the notion that the GE adjustment is “incomplete” or “weak” while abstracting from dynamics. In Section 8, we describe a multi-period extension in which additional rounds require more time. It is then as if the economy moves slowly from point Y to point Z with the passage of time, helping accommodate the complementary notion that GE adjustment “takes time”. Importantly, this mechanism is unlike the one associated with adjustment costs in technologies or preferences: such features modify the underlying PE adjustment and manifest as slow movement from point X to point Y in response to idiosyncratic shocks. By contrast, the mechanism we document explains partial or slow GE adjustment, even if the underlying PE adjustment is complete and instantaneous.

6 Removing Common Knowledge

The preceding analysis offered a simple, and logically coherent, formalization of the notion that the GE adjustment may be weaker than the one predicted by our frictionless benchmark. This formalization, however, built on old ideas about “off equilibrium” adjustment, which find little place in modern methodology. It also required a violation of rational expectations, raising delicate methodological issues, some of which we touch on in Section 9.

---

23 The micro elasticity is the same in the two economies, for they both impose individual rationality and market clearing at the local level.
We now show how the same take-home message of GE attenuation can be obtained, without the aforementioned caveats, by bringing back the REE concept and removing common knowledge of the aggregate shock. In so doing, we not only provide a rationalization of the kind of GE attenuation documented in the previous section, but also address the following elementary question:

*Suppose that the analyst knows the structure of the economy.* Suppose further that the analyst knows the agents in the economy form rational expectations, but does not know the information that may be available to the agents. What predictions can the analyst make about the REE outcomes of the economy?

This question helps clarify what we are after in this section. We are not after higher-order uncertainty (i.e., uncertainty about the beliefs and the behavior of others) per se. Rather, we are after a careful reconsideration of what the REE concept “truly” implies for the response of the economy to the considered shock—where “truly” means without the use of the restrictive, albeit conventional, common knowledge assumption about what the agents know regarding the shock and one another’s information.

We answer this question by studying how the REE outcomes vary with a certain scalar, \( \lambda \in (0, 1] \), which parameterizes the information structure. For any given \( \lambda \), there exists a unique rational-expectations solution; but as we vary \( \lambda \), we also vary the observable properties of this solution. Higher values for \( \lambda \) correspond to higher levels of common knowledge (i.e., less higher-order uncertainty) about the underlying aggregate shock. The standard practice is nested with \( \lambda = 1 \). The key finding is that the GE effect predicted by the standard practice is an upper bound of the GE effect that is predicted when the analyst knows that agents form rational expectations but does not know the details of the information structure upon which these expectations are formed.

### 6.1 Set up

The economy considered in this section shares the same primitives (preferences and technologies) as either the original economy studied in Section 4 or the Tâtonnement variant studied in Section 5. Unlike the latter case, there is no departure from REE. Unlike the former case, the agents do not have common knowledge of the aggregate shock to the underlying fundamentals; instead, they have dispersed, private, information about it.

**Definition 2.** The incomplete-information solution is given by the REE of the economy in which the following is true: for each marketplace \( m \), the information that the agents have in the morning about the underlying shock is summarized in a sufficient statistic \( s_m \) given by

\[
s_m = \Delta \bar{\theta} + v_m,
\]

where \( v_m \) is an idiosyncratic noise term; the latter is drawn from a Normal distribution with mean zero and variance \( \sigma_v^2 \), is i.i.d. across marketplaces, and is independent of \( \Delta \bar{\theta} \).

The signal described above is meant to be a sufficient statistic for all the information that the agents in marketplace \( m \) possess about \( \bar{\theta} \). It therefore encompasses any information contained in the observation of the local \( \theta_m \). Importantly, because this signal differs across marketplaces, the agents in one marketplace do not know what the agents in other marketplaces know. In other words, the agents face, not only (first-order) uncertainty about the underlying shock in the fundamentals, but also (higher-order) uncertainty about what others believe, about what others believe that others believe, and so on.

---

24By this we mean that she knows \((U, \Gamma, e, \rho)\), the associated demand and supply functions, and the validity of Assumptions 1–5.

25This remark echoes related points from Angeletos and La’O (2013), Angeletos and Lian (2016b), and Bergemann and Morris (2013): accommodating higher-order uncertainty in macroeconomic models helps uncover the “true” or “robust” observable properties these models.

26Keep in mind that \( \Delta \bar{\theta} \) is itself drawn from a Normal distribution with mean zero and variance \( \sigma_{\bar{\theta}}^2 \).
The hallmark of this kind of informational friction is the anchoring of higher-order beliefs. Let $E_m[\cdot]$ denote the rational expectation held in the morning by the agents in marketplace $m$. Next, let $\bar{E}^h[\cdot]$ denote that $h$-th order average-expectation operator; this is defined recursively by $\bar{E}^1[\cdot] \equiv \bar{E}[\cdot] \equiv \int E[\cdot] dm$ and $\bar{E}^h[\cdot] \equiv \int E[\bar{E}^{h-1}[\cdot]] dm$ for all $h \geq 2$. For every $m$, $E_m[\Delta \bar{\theta}] = \lambda s_m$, where
\[
\lambda = \frac{1}{1 + (\sigma_1^2/\sigma_m^2)} \in (0, 1].
\]
By aggregating and iterating, we infer that, for all $h \geq 1$, $\bar{E}^h[\Delta \bar{\theta}] = \lambda^h \Delta \bar{\theta}$; equivalently,
\[
\bar{E}^h[\bar{\theta}] = \bar{\theta}_{old} + \lambda^h \Delta \bar{\theta}.
\]
It follows that the scalar $\lambda$ measures, not only how precise the available information about the underlying shock is (equivalently, how close the first-order beliefs of $\bar{\theta}$ are to the true realized value of $\bar{\theta}_{new}$), but also how anchored higher-order beliefs are to the common prior (which is herein centered around $\bar{\theta}_{old}$).

Note that varying $\sigma$ in $[0, +\infty)$ is equivalent to varying $\lambda$ in $(0, 1]$. We can thus think of $\lambda$ as an exogenous parameter. Furthermore, following Bergemann and Morris (2013), it is possible to show that the assumed information structure is without serious loss of generality in the following sense: the predicted GE effect under any Gaussian information structure can be mapped to the one obtained here for some $\lambda \in (0, 1]$.

With the above points in mind, we henceforth characterize the REE as a function of $\lambda$ and interpret the latter as a measure of the degree of common knowledge or, equivalently, as an inverse measure of the informational friction. As $\lambda \rightarrow 1$, the friction vanishes: $\bar{\theta}$ becomes, not only known to each marketplace, but also common knowledge to them. At the other extreme, as $\lambda \rightarrow 0$, the friction is maximal.

For future reference, we finally note the following property. When $\lambda = 1$, $\bar{E}^h[\bar{\theta}] = \bar{\theta}_{new}$ for all $h$, including $h$ arbitrarily high. When instead $\lambda < 1$, we have that $\bar{E}^h[\bar{\theta}] \rightarrow \bar{\theta}_{old}$ as $h \rightarrow \infty$, regardless of how close $\lambda$ is to 1. That is, beliefs of sufficiently high order remain arbitrarily anchored to the pre-shock situation even when the departure from the frictionless benchmark, as measured by the distance of $\lambda$ from 1, is arbitrarily small. Why is this important? Because, as we show next, the rational expectations that agents form about prices turn out to depend, not only on their first-order beliefs of $\bar{\theta}$, but also, and quite importantly, on their higher-order beliefs of $\bar{\theta}$. It is through this channel that lack of common knowledge attenuates the GE effects relative to the frictionless benchmark, thus also reducing the gap between the micro and macro elasticities of interest.

### 6.2 Equilibrium Characterization

Let $E_m[\bar{p}^*]$ denote the rational expectation that agents in marketplace $m$ form about $\bar{p}^*$ in the morning, based on the local knowledge of $s_i$. By Lemma 3, we have that, for all $m$,
\[
q_m = Q(E_m[\bar{p}^*], \theta_m) \quad \text{and} \quad p_m = P(E_m[\bar{p}^*], \theta_m).
\]
That is, the morning outcomes are determined in the same fashion as in our frictionless benchmark, except that the common rational expectation $E[\bar{p}^*]$ is replaced by the local rational expectation $E_m[\bar{p}^*]$. At first glance, this may appear to be an innocuous change. This is indeed the case insofar as one is concerned with the partial-equilibrium predictions of the theory: as we move between the frictionless benchmark and the present variant, we vary the information upon which the rational expectations of $\bar{p}^*$ are formed, but do not vary how $q_m$ and $p_m$ respond either to these expectations or to the local fundamentals. By the same token, the two economies feature the same micro elasticity, that is, the same sensitivity of local activity to local shocks. Yet, as we show next, the two economies make different general-equilibrium predictions and, as a result, feature different macro elasticities.
The aggregate quantity of the morning goods can now be expressed as follows:

\[ \bar{q} \equiv \int q_m dm = Q(\tilde{E}[p^*], \tilde{\theta}) \]  (26)

where \(\tilde{E}[p^*] \equiv \int E_m[p^*] dm\) is the average belief of \(p^*\) in the cross-section of markets. To characterize how \(\bar{q}\) responds to the change in the fundamentals, we therefore need to characterize how this average belief responds. And because agents have rational expectations, this means that we need to characterize the fixed-point relation between the average belief \(\tilde{E}[p^*]\) and the actual \(p^*\). This is similar to our frictionless benchmark, except for the following difference: because agents do not share the same information about aggregate economic conditions, this fixed-point relation turns out to be more “delicate” than before.

Let us elaborate. First, consider how demand and supply are determined in the afternoon markets. At this stage, the quantities of the morning goods are predetermined. By Lemma 2, the afternoon prices satisfy

\[ p^* = P^*(\bar{q}, \bar{\theta}), \]  (27)

where \(P^*\) is defined as in condition (7). Replacing \(\bar{q}\) by (26), we get the following fixed-point relation between the realized value of \(p^*\) and the average expectation of it in the morning:

\[ \tilde{p}^* = T(\tilde{E}[p^*], \tilde{\theta}), \]  (28)

where \(T\) is the same mapping as before. Taking expectations on both sides, we then obtain the following result.

**Lemma 5.** The following fixed-point relation holds in equilibrium:27

\[ \tilde{E}[p^*] = T(\tilde{E}^2[p^*], \tilde{E}[\tilde{\theta}]). \]  (29)

We can now see that, although the REE can still be understood as a fixed point, the precise nature of this fixed point hinges on whether the underlying shock is common knowledge or not. Contrast the above condition to condition (14) obtained in the frictionless benchmark. In that benchmark, the higher-order beliefs of \(\tilde{\theta}, \tilde{p}^*\), or any other variable co-occur with the corresponding first-order beliefs, because all agents shared the same information. Condition (29) then reduces to condition (22), which clarifies how the result above nests the result obtained in the frictionless benchmark. But now note that, once we remove common knowledge of \(\tilde{\theta}\), higher-order beliefs can diverge from first-order beliefs. Furthermore, because realized prices depend on fundamentals and first-order beliefs of prices, the latter depend on first-order beliefs of fundamentals and second-order beliefs of prices, which is what condition (29) states.

Iterating this condition forward, and using the fact that \(T\) is a contraction mapping, we obtain the following characterization of the equilibrium value of \(\tilde{E}[p^*]\).

**Corollary 2.** In equilibrium, the average rational expectation of \(p^*\) is determined by the hierarchy of beliefs about the underlying fundamentals:

\[ \tilde{E}[p^*] = \gamma(1 - \alpha) \sum_{h=1}^{\infty} \alpha^{h-1} \tilde{E}^h[\tilde{\theta}], \]  (30)

where \(\alpha \in (-1, +1)\) is defined as in condition 15 and where \(\gamma \equiv \frac{\partial E[\tilde{p}]}{\partial \tilde{\theta}}\) is the slope of \(\tilde{E}[\tilde{p}^*]\) with respect to \(\tilde{\theta}\) in the frictionless benchmark.

---

27As stated, the result is robust to the introduction of unpredictable shocks between the morning and the afternoon: in the presence of such shocks, condition (28) has to be replaced with \(\tilde{p}^* = T(\tilde{E}[p^*], \tilde{\theta}) + \epsilon\), where \(\epsilon\) captures these shocks. But since these shocks are unpredictable in the morning, Lemma 5 remains valid. This echoes the related point we made in the frictionless benchmark.
Modeling the rational expectations of the endogenous future prices is therefore equivalent to modeling the hierarchy of beliefs of the exogenous fundamentals. By assuming common knowledge of the latter, the standard practice forces higher-order beliefs to collapse to first-order beliefs. This may be convenient, but it is neither realistic nor innocuous: it imposes a very tight structure on the stochastic nature and the observable implications of the REE solution. We next show that relaxing this tight structure by allowing for lack of common knowledge of the underlying shock gives rise to a similar GE attenuation effect as the Tâtonnement modification studied in the previous section.

Remark. To understand the nature of the REE outcomes of our Walrasian economy, it has proved useful to represent the rational expectations of \( \bar{p}^* \) as a functions of the belief hierarchy of \( \bar{\theta} \). To achieve this representation, we iterated on the mapping \( T \). This is akin to relating the Bayesian Nash Equilibrium of an incomplete-information game to its rationalizable outcomes. Note, however, that neither the REE concept in Walrasian economies nor the BNE concept in games require the agents to engage in higher-order reasoning: all that is required is a fixed-point relation between expectations and realized outcomes. From this perspective, what we do throughout this section is merely to characterize this fixed point for an appropriately rich set of possible information structures.

### 6.3 Lack of Common Knowledge as GE Attenuation

By combining Corollary 2 with our earlier characterization of the hierarchy of beliefs, we reach the following characterization of the post-shock rational expectation of \( \bar{p}^* \).

**Lemma 6.** In the unique REE of the economy,

\[
E[\bar{p}^*] = \bar{p}^*_{old} + \pi(\lambda) (\bar{p}^*_{new} - \bar{p}^*_{old})
\]

where \( \bar{p}^*_{old} = P(\bar{\theta}_{old}) \), \( \bar{p}^*_{new} = P(\bar{\theta}_{new}) \), and the function \( \pi \) is continuous and strictly increasing in \( \lambda \), with \( \pi(0) = 0 \) and \( \pi(1) = 1 \).

By varying \( \lambda \), we can thus let the post-shock rational expectation in the modified economy take any value in the range between the corresponding pre- and post-shock values in the frictionless benchmark. This formalizes the following basic point, which we mentioned in the introduction: the rational-expectations hypothesis alone predicts an interval of possible price conjectures; and the standard practice of imposing common knowledge of the shock (\( \lambda = 1 \)) picks the upper bound of this interval.

Using Lemma 6 together with the fact that \( \bar{q} = Q(E[\bar{p}^*], \bar{\theta}) \), we reach the following result, which formalizes the sense in which the assumed friction bridges the gap between the relevant micro and macro elasticities.

**Proposition 4** (Lack of Common Knowledge). For any \( \lambda \), there exists a scalar \( \epsilon_{Inc}(\lambda) \) such that, for any realization \( \Delta \bar{\theta} \) of the aggregate shock, the corresponding change in \( \bar{q} \) is given by

\[
\Delta \bar{q} = \epsilon_{Inc}(\lambda) \Delta \bar{\theta}
\]

Furthermore,

\[
\epsilon_{Inc}(\lambda) = \epsilon^{micro} + \pi(\lambda) (\epsilon^{Macro} - \epsilon^{macro}),
\]

where \( \epsilon^{micro} \) and \( \epsilon^{Macro} \) are the same objects as those found in Proposition 2 and \( \pi \) is the same function as that found in Lemma 6.

Recall that \( \pi \) is continuous and strictly increasing in \( \lambda \), with \( \pi(0) = 0 \) and \( \pi(1) = 1 \). By varying \( \lambda \) between 0 and 1, we can thus span all the values between \( \epsilon^{micro} \) and \( \epsilon^{Macro} \). For \( \lambda \) close to zero (meaning a sufficiently large departure from common knowledge), the macro elasticity of the modified model is arbitrarily close to the micro elasticity of
the original model. But as \( \lambda \) increases (meaning a higher degree of common knowledge), the macro elasticity of the modified model gets closer and closer to the macro elasticity of the original model. Importantly, all these properties hold true no matter whether \( \epsilon_{\text{Macro}} \) is higher or lower than \( \epsilon_{\text{Micro}} \). We conclude that varying the degree of common knowledge is akin to varying the extent to which the GE effect is active, regardless of whether this effect amplifies or offsets the underlying PE effect.

The following is then an immediate corollary of Propositions 3 and 4.

**Corollary 3.** (i) For any Tâtonnement economy with depth \( T \in (0, \infty) \), there exists an incomplete-information economy with common-knowledge degree \( \lambda \in (0, 1) \) such that, for any realization of \( \Delta \tilde{\theta} \), the average rational expectation \( \bar{E}[p^*] \) in the latter coincides with the conjecture \( \tilde{p}^* \) in the former, and the two economies predict the same observable change in \( q \). (ii) The converse is also true.

This equivalence pegs the following question: is there a reason to prefer the one approach over the other? This depends on how much one values rational expectations. We postpone a further discussion of this issue to Section 9.

**Remark 1.** The intuitions we have developed in this section rely on the fact that the unique REE of our economy can be understood as the limit of iterating on the mapping \( T \). To make sure that this limit exists, we required that \( T \) be a contraction mapping or, equivalently, that \( \alpha \in (-1, 1) \). As explained in the next subsection, this means that the REE of our Walrasian economy is also the unique dominance-solvable outcome of a certain game—a property that lends confidence to the obtained predictions. That said, the results presented above (Lemmas 6, Proposition 3, and Corollary 4) extend to \( \alpha \geq -1 \): in this case, the REE is not dominance-solvable, yet it remains unique and continues to exhibit the properties discussed above.

**Remark 2.** In our setting, the necessary informational friction is obtained by assuming that markets are segmented and by preventing agents from observing the prices and/or quantities in markets they do not currently participate in. While these assumptions are certainly stark, it is useful to keep in mind the following points. First, even if markets are centralized, common knowledge may be hard to obtain insofar as the available price signals are sufficiently course relative to the underlying first- and higher-order uncertainty; see Allen, Morris, and Postlewaite (1993) for a thoughtful discussion. Second, even if perfectly precise and public information about the underlying fundamentals and/or the resulting outcomes is readily available, lack of common knowledge about these objects can be the product of “inattention” along the lines of Sims (2003), Mackowiak and Wiederholt (2009), and Myatt and Wallace (2012). That said, a quantitative evaluation of these ideas is beyond the scope of our paper.

### 6.4 Two Additional Results

We conclude this section with two additional results. The first tightens the game-theoretic interpretation of our results; in so doing, it also facilitates the application of Level-k Thinking in the next section. The second sheds additional light on the GE attenuation we have documented in this section.

**Proposition 5.** (i) There exists a linear function \( \mathcal{BR} \) such that, for all realizations of uncertainty and all \( m \), the equilibrium value of \( q_m \) satisfies

\[
q_m = \mathcal{BR} \left( \theta_m, E_m[\theta], E_m[q] \right).
\]

(ii) If \( \bar{q} = \mathcal{BR} (\tilde{\theta}, E[\tilde{\theta}], E[\tilde{q}]) \) and \( \tilde{p}^* = P^* (\tilde{q}, \tilde{\theta}) \), then \( \tilde{p}^* = T(E[\tilde{p}^*], \tilde{\theta}) \); and conversely, if \( \tilde{p}^* = T(E[\tilde{p}^*], \tilde{\theta}) \) and \( \bar{q} = Q(E[\tilde{p}^*], \tilde{\theta}) \), then \( \tilde{q} = \mathcal{BR} (\tilde{\theta}, E[\tilde{\theta}], E[\tilde{q}]) \).

(iii) The slope of \( \mathcal{BR} \) with respect to \( E_m[q] \) equals \( \alpha \), the slope of \( T \).

Part (i) states that the quantity \( q_m \) produced in each market can be expressed as function of \( \theta_m \) (which is locally known), of the local expectation of \( \tilde{\theta} \), and of local expectation of \( \tilde{q} \). Part (ii) states that looking for the fixed point
of these best responses functions is equivalent to looking for the fixed point of $T$, the function that pins down the rational expectations of the relevant prices. Together, these results mean that we can recast the incomplete-information solution of our dynamic Walrasian economy as the unique Bayesian-Nash Equilibrium of a fictitious static game in which the players are the markets, their actions are the local quantities, and their best response functions are given by (33). Complementing this interpretation, part (iii) ties $\alpha$, the slope of the function $T$ whose fixed point pins down the rational expectations of the relevant price, to the degree of strategic complementarity (if $\alpha > 0$) or substitutability (if $\alpha < 0$) in the aforementioned game.

This game is similar to the class of linear-quadratic beauty-contest games considered in, inter alia, Morris and Shin (2002), Angeletos and Pavan (2007) and Bergemann and Morris (2013). A minor twist is that the best response depends on both the beliefs and the actual realization of the underlying fundamentals. The restriction that $\alpha = 0$ guarantees that this game admits a unique rationalizable outcome, which itself coincides with the unique REE outcome of our Walrasian economy. Finally, the magnitude of the strategic complementarity/substitutability in this game can be connected to the magnitude of the GE effect in our Walrasian economy.

This connection is tightest when $\bar{p}^*$ depends on $\bar{q}$ only through $\bar{q}$ (i.e., when $\partial P^*/\partial \theta = 0$). Under this restriction, it is easy to show that

$$\epsilon_{\text{Macro}} = \frac{1}{1 - \frac{\epsilon_{\text{Micro}}}{\epsilon_{\text{Inc}}}}. \tag{34}$$

The macro and micro elasticities therefore share the same sign regardless of $\alpha$, but their relative magnitude depends on $\alpha$. When $\alpha < 0$, the fictitious game features strategic substitutability, the GE effect offsets the PE effect, and our attenuation effect translates to $|\epsilon_{\text{Macro}}| < |\epsilon_{\text{Inc}}| < |\epsilon_{\text{Micro}}|$. When instead $\alpha > 0$, the fictitious game features strategic complementarity, the GE effect amplifies the PE effect, and $|\epsilon_{\text{Macro}}| > |\epsilon_{\text{Inc}}| > |\epsilon_{\text{Micro}}|$.

Perhaps more intriguingly, we now show that, when the gap between $\epsilon_{\text{Macro}}$ and $\epsilon_{\text{Micro}}$ is larger, the fraction of this gap that gets “erased” once one allows lack of common knowledge of the underlying aggregate shock is also larger.

**Proposition 6.** Suppose $\partial P^*/\partial \theta = 0$ and fix $\lambda \in (0, 1)$. A higher $|\alpha|$ drives $\epsilon_{\text{Inc}}/\epsilon_{\text{Macro}}$ further away from 1. That is, the same primitives that enhance the GE effect in the frictionless benchmark also strengthen the attenuation of this effect in the considered variant.

This result follows, in effect, from Corollary 2: by raising the dependence of the equilibrium beliefs of $\bar{p}^*$ on higher-order beliefs, a stronger GE effect makes these beliefs more anchored to $\bar{p}_{old}$, thus also raising the attenuation effect we have formalized in this section.

### 7 Variants: Cobweb, Level-k, and Reflective Equilibrium

So far, we have shown that (i) dropping the assumption that the aggregate shock is common knowledge predicts a reduction of the gap between micro and macro elasticities relative to the frictionless benchmark and (ii) this prediction is shared by a specific relaxation of the REE concept, one that built on Tâtonnement. Clearly, this prediction need not be shared by every relaxation of the REE concept.

For instance, consider the form of “near rationality” suggested by Akerlof and Yellen (1985a) or the closely related concept of “$\epsilon$-equilibrium” (also known as “near-Nash equilibrium”). In games, this concept requires that the action of each player is “nearly rational” in the sense that it delivers a payoff that is within $\epsilon$ of the payoff delivered by the best-response action, where $\epsilon > 0$ is an exogenous scalar that can be thought of as the degree of bounded rationality. Adapting this concept to our Walrasian setting boils down to letting the “nearly rational” demand and supply functions vary around the “fully rational” ones defined in Section 3. As a result, the aggregate change, $\Delta \bar{q}$, triggered by any

---

28To put it differently, the payoff type of player $m$ in the relevant game is given by the pair $(\theta_m, E_m[\bar{q}])$. 

25
given shock can also vary around its frictionless counterpart. It follows the proposed relaxation of the REE concept does not share the aforementioned prediction: the gap between the micro and macro elasticities can be larger in the modified economy than in the frictionless benchmark.

This underscores that the approach we favor in this paper—namely, dropping common knowledge of aggregate shocks while maintaining the REE concept—imposes a specific structure on the departure obtained from the frictionless benchmark. This structure is precisely that the relevant GE effects have to be attenuated.

With this point in mind, we now explore whether this structure is shared by four other possible relaxations of the REE concept, which build on the following concepts from the literature:

1. Cobweb dynamics
3. Reflective equilibrium as in García-Schmidt and Woodford (2015)
4. A form of belief bias as Gabaix (2016)

In all these variants, we preserve the demand and supply system of the frictionless benchmark, as well as its partial-equilibrium predictions. We nevertheless modify the general-equilibrium adjustment to aggregate shocks by letting the agents act on the basis of irrational conjectures about how certain aggregate outcomes react to these shocks. In this regard, the new variants are similar to the Tâtonnement variant studied in Section 5. The difference is in the exact cognitive process that pins down the relevant price and/or quantity conjectures.

We first show that the variants that are based on Cobweb and Level-k Thinking are tightly connected with each other, but not necessarily with our earlier variants: in certain cases, the new variants predict that the relevant price or quantity conjectures can overshoot relative to the frictionless benchmark, which in turn means that the GE effects get amplified instead of being attenuated. We next show that, although the variant that builds on García-Schmidt and Woodford (2015) has a similar flavor as Cobweb and level-k thinking, it avoids the aforementioned “overshooting” problem and ends up delivering similar predictions as our Tâtonnement and incomplete-information variants. We finally discuss how the approach of Gabaix (2016) can also capture the sought-after notion of GE attenuation.

7.1 Cobweb

A familiar alternative to the notion of Tâtonnement dynamics is that of Cobweb dynamics. Similarly to how we treated the former in Section 5, here we recast the latter as an instantaneous cognitive process, whose outcome is a price conjecture \( \hat{p}^* \) upon which the agents act and the morning markets clear.

Define \( \{T^k\}_{k=0}^{\infty} \) recursively by letting \( T^0(p^*, \theta) \equiv p^* \) and \( T^k(p^*, \theta) \equiv T(T^{k-1}(p^*, \theta), \theta) \) for all \( (p^*, \theta) \) and all \( k \in \{1, 2, \ldots\} \). The new solution concept can then be stated as follows.

**Definition 3.** Fix a \( k \in \{0, 1, 2, \ldots\} \). The Cobweb\((k)\) solution is given by a conjecture \( \hat{p}^* \) and by realized outcomes \((q_m, p_m, q_m, p_m)\) for every \( m \) such that the following hold:

(i) The aforementioned outcomes satisfy Lemmas 2 and 3, with \( \hat{E}_m[\hat{p}^*] = \hat{p}^* \) for all \( m \).

(ii) The conjecture \( \hat{p}^* \) is given by

\[
\hat{p}^* = T^k(\hat{p}^*_0, \hat{\theta}_{new}),
\]

where \( \hat{p}^*_0 = \hat{p}^*_old \equiv \mathcal{P}(\hat{\theta}_{old}). \)

The only difference form Definition 1 (our version of Tâtonnement) is the condition that pins down the conjecture \( \hat{p}^* \), namely condition (35) above. When \( k = 0 \), this condition gives \( \hat{p}^* = \hat{p}^*_0 = \hat{p}^*_{old} \), meaning that agents behave under
the conjecture that the average afternoon price will stay at its the pre-shock equilibrium level. Consider next $k = 1$. Now any given agent realizes that, if other agents behave under the aforementioned conjecture, the aggregate quantity in the morning will be $\bar{q} = \bar{q}_0 \equiv Q(\bar{p}^*_0, \bar{\theta}_{\text{new}})$ and the afternoon markets will therefore clear with $\bar{p}^* = P^* (\bar{q}_0, \bar{\theta}_{\text{new}}) = T(\bar{p}^*_0, \bar{\theta}_{\text{new}})$. On the basis of this argument, the initial conjecture is updated from $\bar{p} = \bar{p}^*_0$ to $\bar{p} = \bar{p}^*_1 \equiv T(\bar{p}^*_0, \bar{\theta}_{\text{new}})$. By induction, the conjecture at an arbitrary round $k$ is given by $\bar{p}^*_k = T(\bar{p}^*_{k-1}, \bar{\theta}_{\text{new}}) = T^k(\bar{p}^*_0, \bar{\theta}_{\text{new}})$.

As evident in condition (5), considering a higher $k$ maps to iterating more times on $T$. Because $T$ is a contraction mapping, we know that $\bar{p}^*_{k} \rightarrow \bar{p}^*_{\text{new}}$ as $k \rightarrow \infty$. That is, the Cobweb process shares with the Tâtonnement process that the price conjecture converges to the post-shock equilibrium price as the “depth of reasoning” increases without bound. Unlike the Tâtonnement variant, however, this convergence need not be monotonic and the price conjecture may fall outside the range between the pre- and the post-shock equilibrium price.

**Lemma 7.** There exists a sequence $\{g_k\}$, with $g_0 = 0$ and $\lim_{k \rightarrow \infty} g_k = 1$, such that the following properties hold:

(i) for any $k$ and any $\Delta \bar{\theta}$, the conjecture $\bar{p}^*_k$ satisfies

$$\bar{p}^*_k = \bar{p}^*_{\text{old}} + g_k (\bar{p}^*_{\text{new}} - \bar{p}^*_{\text{old}}).$$

(ii) If $\alpha > 0$, the sequence is strictly increasing and bounded between 0 and 1.

(iii) If instead $\alpha < 0$, this sequence is non-monotone, with $g_k < 1$ when $k$ is even and $g_k > 1$ when $k$ is odd.

The price conjecture therefore falls inside the interval between $\bar{p}^*_{\text{old}}$ and $\bar{p}^*_{\text{new}}$ insofar as the economy features $\alpha > 0$. But if the economy features $\alpha < 0$, the price conjecture can “overshoot” outside this interval. When this happens, the GE effect is amplified, instead of being attenuated, relative to the frictionless benchmark. By the same token, the impact of the shock on $\bar{q}$ can fall outside the interval defined by the micro and macro elasticities of the frictionless benchmark.

**Proposition 7** (Cobweb). For any $k$, there exists a scalar $\epsilon_{\text{Cob}}(k)$ such that, for any realization $\Delta \bar{\theta}$ of the aggregate shock, the corresponding change in the value of $\bar{q}$ that obtains in the Cobweb$(k)$ solution is given by

$$\Delta \bar{q} = \epsilon_{\text{Cob}}(k) \Delta \bar{\theta}$$

Furthermore,

$$\epsilon_{\text{Cob}}(k) = \epsilon_{\text{micro}} + g_k (\epsilon_{\text{Macro}} - \epsilon_{\text{micro}}),$$

where $g_k$ is the same as in Lemma 7, satisfying $g_k > 1$ if $\alpha > 0$ and $k$ is odd and $g_k \in [0, 1)$ otherwise.

We conclude that Cobweb is similar to Tâtonnement and lack of common knowledge in economies in which GE effect complements the PE effect ($\alpha > 0$), but not in economies in which the GE effect offsets the PE effect ($\alpha < 0$): in the latter class of economies, Cobweb opens the door to amplification of the GE effect.

### 7.2 Level-k Thinking

Level-k Thinking—also known as Limited-Depth Thinking—is a solution concept often used in the experimental literature, but also elsewhere.\(^{29}\) According to this concept, level-0 thinkers best-respond to the belief that other players’ strategies are fixed at some “default” point; level-1 thinkers best-respond to the belief that other players are level-0 thinkers; and so on. We adapt this concept to our study of GE effects by building on Proposition 5, which permits us to represent the economy as a game in quantities, and by setting the default point for the average quantity $\bar{q}$ to its pre-shock equilibrium level. In particular, we define $\{BR^k\}_k$ recursively by $BR^0(\theta_{\text{m}}, \theta, q) \equiv q$ and

\[ \mathcal{BR}^k(\theta_m, \theta, q) \equiv \mathcal{BR} \left( \theta_m, \theta, \mathcal{BR}^{k-1}(\theta, q) \right) \]
for all \((\theta_m, \theta, q)\) and all \(k \geq 1\), where \(\mathcal{BR}\) is itself defined as in Proposition 5, and state our solution concept as follows.

**Definition 4.** For any \(k \in \{0, 1, 2, \ldots\}\), the level-\(k\) solution is given by a quantity conjecture \(q\) and by realized outcomes \((q_m, p_m, q^*_m, p^*_m)\) for every \(m\) such that the following hold:

(i) The aforementioned outcomes satisfy Lemmas 2 and 3, with \(\hat{E}_m[p^*] = P^*(q, \hat{\theta}_{new}) \forall m\).

(ii) The quantity conjecture \(q\) is given by

\[ q = \mathcal{BR}^k(\hat{\theta}_{new}, \hat{\theta}_{new}, q_{old}), \]  

(37)

where \(q_{old} = Q(\hat{p}^*_m, \hat{\theta}_{old})\).

Let us explain this definition. When \(k = 0\), agents expect the aggregate quantity to stay at its pre-shock equilibrium value; that is, \(q = q_0 \equiv q_{old}\). When \(k = 1\), agents expect the other agents to act as if \(k = 0\) and therefore expect the aggregate quantity to be given by the best response to \(q_{old}\); that is, \(q = \hat{q}_1 \equiv \mathcal{BR}(\hat{\theta}_{new}, \hat{\theta}_{new}, q_{old})\). Similarly, for any \(k \geq 1\), agents expect the aggregate quantity to be \(q = \hat{q}_k \equiv \mathcal{BR}(\hat{\theta}_{new}, \hat{\theta}_{new}, \hat{q}_{k-1})\). This mirrors the definition of level-k thinking in games and explains part (ii).\(^{30}\) Part (i) then transforms the quantity conjecture to a price conjecture and requires that demand and supply are based on this price conjecture: whenever an agent expects the aggregate morning quantity to be \(q\), she also expects the average afternoon price to be \(P^*(q, \hat{\theta}_{new})\), and chooses her demand or supply accordingly.

Forming conjectures about the simultaneous behavior of the other agents is therefore equivalent to forming conjectures about the resulting future prices. This permits us to go back and forth between the game-theoretic and the Walrasian representation of the economy under the level-k concept. Furthermore, because iterating on the best-response function \(\mathcal{BR}\) is equivalent to iterating on the contraction mapping \(\mathcal{T}\), it is evident that there is tight relation between the level-k and Cobweb solution concepts. This point is formalized in the following proposition.

**Proposition 8.** Suppose either that \(P^*(q, \hat{\theta})\) is invariant to \(\hat{\theta}\), or that we modify the Cobweb concept so that the initial price conjecture is given by \(\hat{p}_0 = P^*(q_{old}, \hat{\theta}_{new})\) rather than \(\hat{p}_0 = \hat{p}^*_{old} = P^*(\hat{q}_{old}, \hat{\theta}_{old})\). Then, for any \(k \in \{0, 1, 2, \ldots\}\), the level-k solution and the Cobweb\((k)\) solution impose the same price conjectures and give rise to the same observables.

The two concepts are not tautologically the same: Level-k Thinking is defined in the space of beliefs about the actions of other players, whereas Cobweb is defined in the space of price conjectures. Furthermore, a minor discrepancy between the two emerges when \(\hat{p}^*_{old} \neq P^*(q_{old}, \hat{\theta}_{new})\), because the two iterative procedures then start from different initial guesses (or “default points”). This explains why the equivalence between the two has to be qualified by the first sentence in the above proposition. Notwithstanding these points, the essence of the two concepts is the same, and so are their implications with regard to the response \(q\) to the aggregate shock.

**Corollary 4.** Suppose \(\partial P^*/\partial \theta = 0\). Similarly to Cobweb, Level-k Thinking attenuates the GE adjustment and reduces the gap between micro and macro elasticities in economies in which the GE effect amplifies the PE effect \((\alpha > 0)\), but not in economies in which the GE effect offsets the PE effect \((\alpha < 0)\).

We illustrate this point in Figure 3. The left panel features strategic complementarity \((\alpha > 0)\), the right one features strategic substitutability \((\alpha < 0)\). In either panel, the solid blue lines represent the best-response function \(\mathcal{BR}\) before and after the shock; \(\bar{q}_0\) identifies the pre-shock REE quantity; and \(\bar{q}_\infty\) identifies the post-shock REE quantity. The PE effect of the shock is captured by the vertical shift from point \(X\) to point \(Y\). The frictionless GE effect is captured by

\(^{30}\)Note that, when every agent expects the aggregate quantity to be \(q\), part (ii) of the definition together with Lemma 3 implies that the realized aggregate quantity is \(\bar{q} = \mathcal{BR}(\hat{\theta}_{new}, \hat{\theta}_{new}, q)\). This in turn explains why the assumed conjectures satisfy the recursion \(\hat{q}_k \equiv \mathcal{BR}(\hat{\theta}_{new}, \hat{\theta}_{new}, \hat{q}_{k-1})\) for all \(k \geq 1\).
the shift from $Y$ to $Z$. Note that the GE effect amplifies the PE effect when $\alpha > 0$ and offsets it when $\alpha < 0$. Finally, the dashed arrows represent the rounds of level-k thinking: level-0 is captured by the shift from $X$ to $Y$ (level-0 coincides with PE); level-1 is captured by the shift from $Y$ to $Y'$; and so on. It is then evident that level-k thinking helps capture the notion of incomplete GE adjustment when $\alpha > 0$, but opens the door to “GE overshooting” when $\alpha < 0$.\footnote{Corollary 4 and the figure assume $\partial P^*/\partial \theta = 0$. If we relax this assumption, the aforementioned overshooting can obtain even when $\alpha > 0$.}

Remark. Like Garcia-Schmidt and Woodford (2015), we view the aforementioned overshooting as a “pathological” prediction. If we allow $\alpha \leq -1$, Level-k Thinking produces an additional pathology: the conjectured prices/quantities diverge away from their REE counterparts as the depth of reasoning increase. In the next subsection, we explain how both of these problems are cured by an amendment proposed by Garcia-Schmidt and Woodford (2015). It is worth noting, however, that none of these problems emerge with our preferred approach, namely the one that maintains rational expectations but removes common knowledge of the shock.

7.3 Reflective Equilibrium

We now turn attention to “reflective equilibrium”, a concept that is closely related to Level-k Thinking but bypasses the aforementioned pathologies. This concept was originally developed by Garcia-Schmidt and Woodford (2015) in the context of the New-Keynesian model and was used to shed new light on the macroeconomic effects of monetary policy. Putting aside the details of the considered application, the more general idea is to let the subjective conjecture of a certain variable—inflation in their context—to adjust continuously with the difference between the conjecture itself and the value of that variable that gets realized if all agents act on the basis of that conjecture. For our purposes, we identify the relevant variable with the average afternoon price and adapt the solution concept of Garcia-Schmidt and Woodford (2015) as follows.

**Definition 5.** Fix a $T \in (0, \infty)$. The level-$T$ reflective equilibrium is given by a conjecture $\hat{p}^*$ and by realized outcomes $(q_m, p_m, q_m^*, p_m^*)$ for every $m$ such that the following hold:

(i) The aforementioned outcomes satisfy Lemmas 2 and 3, with $\hat{E}_m[p^*] = \hat{p}^*$ for all $m$.

(ii) The conjecture $\hat{p}^*$ is given by $\hat{p}^* = \hat{P}^*(T)$, where the function $\hat{P}^*$ is obtained by solving the following ODE:

$$\frac{d\hat{P}^*(t)}{dt} = T \left( \hat{P}^*(t), \hat{\theta} \right) - \hat{P}^*(t) \quad \forall t \geq 0$$

(38)

with initial condition $\hat{P}^*(0) = \hat{p}_{old}^* \equiv \mathcal{P}(\theta_{old})$.\footnote{Corollary 4 and the figure assume $\partial P^*/\partial \theta = 0$. If we relax this assumption, the aforementioned overshooting can obtain even when $\alpha > 0$.}
To interpret the above, note that, for every $t$, $T (\hat{P}^*(t), \hat{\theta})$ gives the actual average price that clears the market for afternoon goods when the quantity $\hat{q}$ is determined under the (incorrect) conjecture that this price equals $\hat{P}^*(t)$. Condition (38) therefore requires that the conjecture is adjusted upwards if the “actual” price exceeds the conjectured one, and downwards otherwise. The assumed concept is therefore similar to adaptive expectations, except that the adjustments happen instantaneously and on the basis of hypothetical outcomes, as opposed to with the passage of calendar time and on the basis of the observation of actual past outcomes.

The assumed concept also resembles Cobweb dynamics and Level-k Thinking in the follow regard: the conjectured outcome is adjusted in the direction of the realized outcome. But whereas Cobweb and Level-k require the adjustment to be in discrete steps, with the conjecture in each round being replaced by the implied outcome in the previous round, Reflective Equilibrium lets the adjustment happen at infinitesimally small steps. This guarantees that the conjecture never overshoot relative to the frictionless benchmark, thus bypassing the aforementioned “pathology” of the Cobweb and level-k concepts: as we vary $T$, the price conjecture spans the entire interval between $\bar{p}_{old}$ and $\bar{p}_{new}$, in a continuous manner, and without ever overshooting outside of it, regardless of $\alpha$. By the same token, the GE effect is necessarily attenuated, and the following is true.

**Proposition 9** (Reflective Equilibrium). For any $T \in (0, \infty)$, there exists a $T' \in (0, \infty)$ and a $\lambda \in (0, 1)$ such that the level-$T$ reflective equilibrium coincide with the Tâtonnement($T'$) solution, and both of them predict the same aggregate outcomes as the incomplete-information variant with common-knowledge degree $\lambda$.

In the above, we have adapted the solution concept of Garcia-Schmidt and Woodford (2015) in the space of price conjectures. Clearly, the same results obtain if we recast it in the space of quantity conjectures. That is, if we let the conjecture be $\hat{q} = \hat{Q}(T)$, where the function $\hat{Q}$ is obtained by solving the following ODE:

$$\frac{d\hat{Q}(t)}{dt} = \mathcal{BR} (\hat{\theta}_{new}, \hat{\theta}_{new}, \hat{Q}(t)) - \hat{Q}(t) \quad \forall t \geq 0$$

with initial condition $\hat{Q}(0) = \bar{q}_{old}$. Under this perspective, the cognitive process we have introduced here can be thought of as a smooth version, not only of our variant that was based on Cobweb, but also of the one that was based on Level-k Thinking. As already noted, it is this smoothness that avoids the overshooting problem of Level-k Thinking.

**Remark 1.** In Section 2.4 of their paper, Garcia-Schmidt and Woodford (2015) discuss extensively how their solution concept is a “smooth” version of Level-k Thinking, as well as how it relates to the earlier work of Evans and Ramey (1992, 1995). In the Appendix, they also use an example to illustrate how the Level-k solution may oscillate around the REE solution and may diverge away from it as $k$ increases. Under the lenses of our framework, that example maps to the case in which $\alpha < -1$: in this case, the Level-k conjectures diverge to plus or minus infinity as $k \to \infty$, whereas the reflective equilibrium converges to the REE solution as $T \to \infty$. Our results in this section complement Garcia-Schmidt and Woodford (2015), not only by offering a sharper illustration of these particular points, but also by connecting their contribution to broader theme of our paper—GE attenuation—and by building a bridge that paper Garcia-Schmidt and Woodford (2015) and the literature on higher-order uncertainty.

**Remark 2.** Garcia-Schmidt and Woodford (2015) are primarily concerned with the limit as $T \to \infty$, which they use as a refinement of the REE set: they study a New-Keynesian model that admits multiple rational-expectations equilibria, only one of which is selected by their concept if one starts from a default point within an appropriate set and takes the limit as $T \to \infty$. In our framework, the rational-expectations equilibrium is unique, so there is no selection issue. The question of whether and how higher-order uncertainty may rationalize the particular selection made by Garcia-Schmidt and Woodford (2015) is certainly intriguing, but is beyond the scope of our paper.
7.4 Cognitive Discounting

Gabaix (2016) departs from the REE concept by assuming that the perceived law of motion of the aggregate state of the economy is less responsive to the underlying aggregate shocks than the actual law of motion. To be concrete, consider a dynamic model in which the aggregate state variable, de-trended around its steady state and denoted by $x_t$, evolves according to the following law of motion: $x_{t+1} = G(x_t, \epsilon_{t+1}) = Ax_t + B\epsilon_{t+1}$, where $A$ and $B$ are matrices and $\epsilon_{t+1}$ is an exogenous innovation. Gabaix (2016) assumes that the “behavioral agent” incorrectly perceives the law of motion to be $x_{t+1} = \mu G(x_t, \epsilon_{t+1})$, for some exogenous scalar $\mu \in (0, 1)$. The latter is interpreted as a form of “cognitive discounting”. Gabaix (2016) then proceeds to study the implications of introducing this kind of belief bias within the New Keynesian model.

We adapt this kind of belief bias in our own setting as follows. To simplify the exposition, normalize $\tilde{p}_{old}^* = 0$. Next, assume that the conjecture $\tilde{p}^*$ is given by the solution to the following fixed-point problem:

$$\tilde{p}^* = \mu T(\tilde{p}^*, \theta_{new});$$

for some $\mu \in (0, 1)$. To interpret the above, note that $T(\tilde{p}^*, \theta_{new})$ gives the actual realization of the endogenous variable of interest when the agents’ conjecture of this variable is set $\tilde{p}^*$. Rational expectations impose that the conjecture and the realization coincide: $\tilde{p}^* = T(\tilde{p}^*, \theta_{new})$. The variant proposed above, instead, requires that the conjecture differs from the realization by a discount factor equal to $\mu \in (0, 1)$. This mirrors the assumption made in Gabaix (2016).

By solving the above fixed point, one can show that $\tilde{p}^*$ satisfies the following restriction:

$$\tilde{p}^* = \tilde{p}_{old}^* + \pi(\mu) (\tilde{p}_{new}^* - \tilde{p}_{old}^*)$$

where $\pi$ is the same function as the one defined in Lemma 6. That is, the irrational conjecture generated by the Gabaix-like variant coincides with the average rational expectation in our earlier incomplete-information variant when $\lambda = \mu$. As a result, the two variants make the same predictions about

Proposition 10. For any Gabaix-like variant with discount $\mu \in (0, 1)$, there exists an incomplete-information economy with parameter $\lambda = \mu$ such that, for any realization of $\Delta \bar{q}$, the average rational expectation $\bar{E} [\tilde{p}^*]$ in the latter coincides with the irrational conjecture $\tilde{p}^*$ in the former, and the two economies predict the same observable change in $\bar{q}$. The converse is also true.

This exact form of equivalence need to extend to the dynamic models studied in Gabaix (2016) or some of our companion work (Angeletos and Lian, 2016a). It nevertheless illustrate that the kind of irrational belief bias assumed in Gabaix (2016) plays a similar modeling role, and has similar observable implications, as the rational belief anchoring that is present in our work and in the related literature on incomplete information and higher-order beliefs.

From this perspective, the two approaches can be seen as close substitutes to one another vis-a-vis the goal of attenuating GE effects. Note, however, the following subtlety. In the approach described above, nothing prevents us from assuming that $\mu > 1$ instead of $\mu < 1$: a “behavioral” agent may incorrectly perceive either the endogenous state reacts less or that it reacts more than what it actually does. This means that, although one can obtain the sought-after result (attenuation of GE effects) by assuming the “right” kind of belief distortion, one can also obtain the opposite result (amplification of the GE effects) simply by assuming the opposite kind of belief distortion. This echoes our earlier comment about Akerlof and Yellen (1985a,b) and $\epsilon$-equilibrium.

For better or worse, our preferred approach does not provide this degree freedom: because the variation in higher-order beliefs is necessarily bounded by the variation in first-order beliefs, our approach predicts the potency of the GE effects in the absence of common knowledge is necessarily lower than in the frictionless benchmark.
Remark. Gabaix (2016) contains two modifications of the standard modeling practice: the one that we have considered above; and another that we have abstracted from. The latter is the kind of “sparsity” formalized in Gabaix (2014): relative to a fully rational agent, the “sparse” agent responds less to any variation in the variables that enter her individual decision problem (prices, income, etc). This represents a decision-theoretic friction, which is distinct both conceptually and empirically from the belief-related friction we have isolated in the present analysis.\(^{32}\)

8 GE Adjustment Takes Time

In the preceding analysis, we formulated the idea of weak GE adjustment. We now formulate the complementary idea of slow GE adjustment. To this goal, we introduce a variant framework, in which GE interactions happen repetitively, that is, over multiple periods after the shock has hit the economy. Like our baseline framework, the new framework is not meant to be either general or realistic. Rather, it is designed so as to facilitate (i) the adaptation of our earlier insights to a dynamic context and (ii) some additional comparisons of the considered methodological approaches.

8.1 Set Up

There is a continuum of marketplaces, indexed by \(m \in [0,1]\), a double continuum of households, indexed by \(i = (i_1, i_2) \in [0,1] \times [0,1]\), and multiple periods, indexed by \(t \in \{0, 1, 2, \ldots, T\}\).\(^{33}\) To simplify the exposition, we let \(T = \infty\).\(^{34}\) At any given point of time, each marketplace is populated by a measure one of households and a representative firm. Households may randomly from one marketplace to another as time passes and are the key decision-theoretic units in the model; firms are immobile and play an auxiliary role.

Households consume two goods in each period: leisure and a local final good. The latter is produced by the local firm in each marketplace, using the locally available labor and capital. Capital takes the form of multiple, imperfectly-substitutable, varieties. Each household is capable of transforming the final good into a single variety of capital, which can be used into production next period. The efficiency of this transformation depends on a local fundamental, which is specific to each marketplace but stays constant over time.\(^{35}\) We denote the fundamental of marketplace \(m\) by \(\theta_m\) and the corresponding aggregate by \(\bar{\theta}\).

**Marketplaces and matching.** As in our baseline framework, the assumptions that markets are segmented but households can randomly relocate for one marketplace to another help disentangle partial- and general-equilibrium effects. To keep the analysis tractable, we now model the relocation of household as the product of random pairwise matching across the marketplaces.

At \(t = 0\), there is a given allocation of households across the marketplaces. This allocation is such that each marketplace is populated by an equal measure of households. At the start of each period \(t \geq 1\), each marketplace \(m\) is matched with another, randomly chosen, marketplace \(m'\). At this point, a fraction \(1 - \rho\) of the population from marketplace \(m\) relocates to marketplace \(m'\), and vice versa. Every household that relocates brings with her the capital she had accumulated in her old home. Following this relocation, the match is dissolved and each marketplace operates its own markets for the labor, the capital and the final good.

\(^{32}\)Gabaix has explained to us that he sees the two frictions as two facets of the same cognitive limitation. We, instead, prefer to see them as separate frictions at least for pedagogical reasons: one can accommodate inattention or any other adjustment friction in the decision rules (or the best responses) of an agent without dropping the REE (or Nash Equilibrium) solution concept, and vice versa. Also note one can shut down the one or the other friction in Gabaix (2016) by appropriately picking the relevant free parameters of his model. For example, setting \(m_o = m_r = 1\) recovers the standard decision rules (shuts down inattention), whereas letting \(M < 1\) (respectively, \(M > 1\)) allows for under-reaction (respectively, over-reaction) in the perceived law of motion of the behavior of others.

\(^{33}\)Note that \(t\) and \(T\) now refer to calendar time. This should not be confused with the notation used in Section 5, where \(t\) and \(T\) referred to the number of iterations (or the depth) of Tâtonnement-like cognitive process.

\(^{34}\)We think of the overall time horizon as relatively short. But whether this means few months or few quarters cannot be addressed in this paper.

\(^{35}\)Note the subtle change relative to our baseline model: the fundamental is now fixed to the marketplace rather than to the individual. This change is made only for the purpose of simplifying the information structure, which now evolves endogenously over time.
We let $M(i, t)$ denote the marketplace in which household $i$ is located during period $t$. We let $I(m, t)$ denote the set of households who trade at marketplace $m$ during period $t$. We finally adopt the convention that household $i = (i_1, i_2)$ is located at marketplace $m = i_1$ at $t = 0$; that is, $M(i, 0) = i_1$.

**The firms.** In each period $t$ and each marketplace $m$, there is a competitive final-good firm, which employs the capital varieties and the labor of the households in $I(m, t)$. The produced quantity of the final good is given by

$$q_{m, t} = \kappa_{m,t} \ell_{m,t}^{1-\omega},$$

where $\ell_{m,t}$ is the local supply of labor,

$$\kappa_{m,t} \equiv \left( \int_{i \in I(m,t)} k_{i,t-1}^{\sigma-1} \frac{dI}{k_{i,t-1}} \right)^{\sigma-1},$$

is a CES composite of the local capital varieties, $k_{i,t-1}$ denotes the quantity of the capital variety owned and supplied by household $i$ (note that this is determined in the previous period), $\sigma > 0$ is the elasticity of substitution across varieties, and $\omega \in (0, 1)$ is the capital share. Normalizing the price of the final good to one, we can therefore express the profits of the final-good firm in marketplace $m$ and period $t$ as

$$q_{m, t} - w_{m, t} \ell_{m, t} - \int_{i \in I(m, t)} p_{m, i, t} k_{i, t-1} \, di,$$

where $w_{m, t}$ denotes the local wage and $p_{m, i, t}$ denotes the local price of the capital variety supplied by household $i$.

**The households.** Consider household $i$. Her preferences are given by

$$\sum_{t=0}^{\infty} \beta^t U(c_{i,t}, n_{i,t}),$$

where $\beta \in (0, 1)$ is her discount rate, $c_{i,t}$ denotes her consumption, $n_{i,t}$ denotes her labor supply, and $U$ is the per-period utility function, given by $U(c,n) = c - \frac{1}{1+\eta}$ for some $\eta > 0$. The period-$t$ budget constraint is given by

$$c_{i,t} + f(k_{i,t}, \theta_m) = y_{i,t} \equiv w_{m,t} n_{i,t} + p_{m,i,t} k_{i,t-1}, \quad \text{with} \quad m = M(i, t).$$

To interpret the above, recall first that $M(i, t)$ denotes the marketplace in which the household is located during period $t$. Next, note that $w_{m,t} n_{i,t}$ and $p_{m,i,t} k_{i,t-1}$ are, respectively, her labor and capital income. Finally, $\Gamma(k_{i,t-1}, \theta_m)$ is the cost of transforming the final good into the household’s capital variety. We let $\Gamma(k, \theta) = \theta^{-\phi} k^{1+\phi} \theta$, for some $\phi > 0$. A “better” fundamental therefore means a lower cost of transforming the final good into capital.

**Log-linearization and shocks.** As in our earlier analysis, we henceforth re-interpret all the variables as log-deviations from a symmetric steady state and we work with the log-linearized version of the model. We also consider a once-and-for-all shock to $\theta$ from some $\bar{\theta} = \hat{\theta}_{old}$ to some $\bar{\theta} = \hat{\theta}_{new} \neq \hat{\theta}_{old}$. We treat the initial fundamental, $\hat{\theta}_{old}$, as a fixed parameter and the change, $\Delta \theta \equiv \hat{\theta}_{new} - \hat{\theta}_{old}$, as a random variable drawn from a Normal distribution centered around 0. We denote the corresponding change in the local fundamentals by $\Delta \theta_m$. We finally use a bar over any variable to indicate the economy-wide average of that variable.\(^{36}\)

**From elasticities to IRFs.** In what follows, we investigate how the economy’s outcomes (investment, output, etc) respond to the aforementioned shock, not only on impact (at $t = 0$) but also in all future periods ($t \geq 1$). This exercise is similar to the one conducted before, except that now the key theoretical object is an entire impulse response function (IRF), describing the change in economic outcomes at each $t \geq 0$, as opposed to a single elasticity scalar.

\(^{36}\)That is, $q_t \equiv \int q_{m,t} \, dm$, $\bar{p}_t \equiv \int p_{m,t} \, dm$, $k_{t-1} \equiv \int k_{m,t-1} \, dm$ and so on. We also use the convention that $k_{-1} = 0$. 
8.2 Preliminaries

We start the analysis by imposing Assumptions 1–4. These assumptions suffice for obtaining the following result, which represents the partial-equilibrium predictions of the model.

Lemma 8. (i) There exists a known linear vector function $F$ such that, for every $m$ and every $t$,

$$(q_{m,t}, \ell_{m,t}, w_{m,t}, p_{m,t}) = F(k_{m,t}).$$

(ii) There exists a known linear function $K$ such that, for every $m$ and every $t$,

$$k_{m,t} = K(E_{m,t}[\hat{p}_{t+1}], \theta_m)$$

where $E_{m,t}[\cdot]$ denotes the period-$t$ subjective expectation of the agents located in marketplace $m$ during that period.

Part (i) gives the local output, employment, and prices in each period and each marketplace as functions of the local capital stock. Part (ii) gives local investment as a function of the local subjective beliefs of a key general-equilibrium object, the average price of capital next period. To pin down outcomes, what remains to do is to specify how these subjective beliefs are formed and how they adjust to the underlying aggregate shock. We do so in the sequel, under different assumptions about the solution concept and/or the level of common knowledge in the economy.

8.3 Frictionless Benchmark

Similarly as in Section 4, we define the frictionless benchmark by imposing the REE concept together with common knowledge of $\theta$ and of $\hat{p}_t$ for all $t$.

In the Appendix, we show that there exists a linear function $T$ such that, in any equilibrium and any $t \geq 1$,

$$\hat{p}_t = T(p_t, \theta).$$

The slope of $T$ is given by

$$\alpha \equiv \frac{\partial T}{\partial p} = \frac{(1 - \sigma \chi)(1 - \rho^2)}{\sigma \phi + \sigma \chi \rho^2 + (1 - \rho^2)},$$

where $\chi = \frac{\sigma(1 - \omega)}{\sigma + \sigma \chi}$. The mapping $T$ and the scalar $\alpha$ have similar interpretations as the corresponding objects in our baseline model, although they of course admit different functional forms.

It is easy to verify that $\alpha$ is necessarily less than $+1$; it can be either positive or negative, and is higher than $-1$ as long as $\phi$ is high enough and/or $\sigma$ is low enough. We henceforth assume that the latter property holds so as to guarantee that $T$ defines a contraction mapping. We then have that $\hat{p}_t = \mathcal{P}(\theta)$ for all $t \geq 1$, where $\mathcal{P}$ is the fixed point of $T$. Using this into part (ii) of Lemma 8, we infer that, for all $m$ and all $t \geq 0$,

$$k_{m,t} = K(\mathcal{P}(\theta), \theta_m) \quad \text{and} \quad \bar{k}_t = K(\theta) \equiv K(\mathcal{P}(\theta), \bar{\theta}).$$

From part (i) of Lemma 8, we can then express the local outcomes $(q_{m,t}, \ell_{m,t}, w_{m,t}, p_{m,t})$ as linear functions of the pair $(k_{m,t}, \theta_m, \bar{\theta})$ and the corresponding aggregates as linear functions of $\bar{\theta}$ alone.\(^{37}\)

---

\(^{37}\)To be precise, these assumptions are adapted to the multi-period framework of this section by allowing the agents to have arbitrary subjective beliefs, not only of current and future outcomes in other marketplaces, but also of any unobserved past outcomes; and by imposing market clearing to the markets for the consumption good, labor, and capital in all periods.

\(^{38}\)Given that $\rho \in (0, 1)$, we have that $\alpha \in (0, 1)$ if and only if $\sigma \chi < 1$, $\alpha = 0$ if and only if $\sigma \chi = 1$, and $\alpha < 0$ if and only if $\sigma \chi > 1$.

\(^{39}\)Given that $\phi \in (0, 1)$, we have that $\alpha \in (0, 1)$ if and only if $\sigma \chi < 1$, $\alpha = 0$ if and only if $\sigma \chi = 1$, and $\alpha < 0$ if and only if $\sigma \chi > 1$.

\(^{40}\)When $\phi + \chi(2\rho^2 - 1) \geq 0$, $\alpha > -1$ regardless of $\sigma$; and when $\phi + \chi(2\rho^2 - 1) < 0$, $\alpha > -1$ if and only if $\sigma < \hat{\beta}$, for some $\hat{\beta} > 1$.

Note that local outcomes vary both in the cross section and over time due to the cross-section heterogeneity in $\theta_m$ and the random relocation of agents. Aggregate outcomes, by contrast, are time invariant.
We are now ready to characterize the response of the economy to the aggregate shock. Without serious loss of
generality, we focus on investment as the observable quantity of interest. Think of this as the analogue of the “morning
quantity” in our baseline model. The responses of all other variables (output, employment, prices) can be inferred
from Lemma 8 and feature a similar disconnect between micro and macro effects. To allow for a non-zero GE effect,
we finally assume that \( \alpha \neq 0 \).

**Proposition 11.** There exist scalars \( \epsilon_{\text{Macro}} \) and \( \epsilon_{\text{Micro}} \), with \( \epsilon_{\text{Macro}} \neq \epsilon_{\text{Micro}} \), such that

\[
\bar{k}_t = \bar{k}_{\text{new}} = \bar{k}_{\text{old}} + \epsilon_{\text{Macro}} \Delta \bar{\theta} \forall t \quad \text{and} \quad k_{m,t} = \bar{k}_{\text{new}} + \epsilon_{\text{Micro}} (\Delta \bar{\theta}_m - \Delta \bar{\theta}) \forall m, t.
\]

The first equation characterizes the response of aggregate investment. On impact, \( \bar{k}_t \) jumps from \( \bar{k}_{\text{old}} \equiv \mathcal{K}(\bar{\theta}_{\text{old}}) \) to \( \bar{k}_{\text{new}} \equiv \mathcal{K}(\bar{\theta}_{\text{new}}) \) and stays constant thereafter. In other words, the IRF of aggregate investment is flat at a level equal
to \( \epsilon_{\text{Macro}} \). The scalar \( \epsilon_{\text{Macro}} \) therefore has a similar meaning as the macro elasticity in our baseline framework, except
that it now indexes the entire dynamic response of the economy.\(^41\)

The second equation shifts attention to the cross section and identifies the scalar \( \epsilon_{\text{Micro}} \) as the analogue of the micro
elasticity in our baseline framework: this scalar summarizes the IRF of local investment to local shocks or, equivalently,
the local exposure to the aggregate shock.

The two scalars differ from each other because of the GE effect associated with the mobility of capital across
marketplaces. Depending on parameters, this GE effect can cause \( \epsilon_{\text{Macro}} \) to be either higher or lower than \( \epsilon_{\text{Micro}} \). Intuitively, there are two opposite forces at work. On the one hand, investment choices tend to be strategic substitutes
because an increase in the aggregate capital stock raises wages and depresses the aggregate return to capital. On the
other hand, investment choices tend to be strategic complements because an increase in the aggregate capital stock
raises the demand for each individual variety (insofar as the different varieties are imperfect substitutes in production).

When the first effect dominates, \( \alpha < 0 \) and \( \epsilon_{\text{Macro}} < \epsilon_{\text{Micro}} \); otherwise, \( \alpha < 0 \) and \( \epsilon_{\text{Macro}} > \epsilon_{\text{Micro}} \).

**Remark.** In our setting, the frictionless benchmark lacks any interesting dynamic patterns in the responses either
due to adjustment frictions in our setting by letting the cost of investment depend on the local capital stock.

---

### 8.4 Tâtonnement Dynamics

In the aforementioned benchmark, \( \bar{k}_t \) jumps from \( \bar{k}_{\text{old}} \) to \( \bar{k}_{\text{new}} \) as soon as the aggregate shock hits the economy. Behind this instantaneous adjustment in quantities, there is an instantaneous adjustment in the expected and the actual
price of capital: \( \mathbb{E}_t[\bar{p}_{t+1}] \) and \( \bar{p}_{t+1} \) alike jump from \( \bar{p}_{\text{old}} = \mathcal{P}(\bar{\theta}_{\text{old}}) \) to \( \bar{p}_{\text{new}} = \mathcal{P}(\bar{\theta}_{\text{new}}) \). We now illustrate how this
adjustment can be slowed down by letting the relevant price conjectures adjust according to Tâtonnement dynamics.

The methodological strategy is similar to the one taken in Section 5, except that now the cognitive process takes
place in “real time”. In particular, the relevant conjecture here is \( t \) further updates of the initial conjecture of
\( \bar{p}_t \) occur only with the passage of the calendar time. The details are spelled out in Appendix C. Here, we describe the basic
ideas with the help of Figure 4.

We consider two different economies: the economy in the left panel features \( \epsilon_{\text{Macro}} > \epsilon_{\text{Micro}} > 0 \), meaning that the
GE effect reinforces the PE effect; the economy in the right panel features the opposite property. For each economy,

\(^{41}\) Aggregate employment and output exhibit the same dynamic response as \( k_t \), lagged by one period and scaled by a constant factor.

\(^{42}\) One can accommodate such adjustment frictions in our setting by letting the cost of investment depend on the local capital stock.
Figure 4: GE adjustment takes time. (Left panel: GE amplifies PE. Right panel: GE offsets PE.)

We draw the IRF of \( k_t \) under two scenarios: the Tâtonnement variant under consideration (solid red line), and the frictionless benchmark (dashed blue line). In that benchmark, \( k_t \) jumps up by a quantity equal to \( \varepsilon_{\text{Macro}} \) and stays at this higher level for ever after. In the Tâtonnement variant, instead, the initial jump in \( k_t \) is approximately equal to \( \varepsilon_{\text{Micro}} \). Depending on which economy we consider, this initial response can represent either an under-reaction or an over-reaction relative to the frictionless benchmark. In either case, however, it reflects the attenuation of the underlying GE effect. This echoes the result of Section 5. What’s new here is that this attenuation decreases over time: because the “Walrasian auctioneer” inside the mind of each agent updates the conjecture of \( p_t \) as \( t \) increases, the distance between between the two IRFs decreases with \( t \) and eventually vanishes.

8.5 Dynamics with Incomplete Information

We find the preceding variant to be useful for two reasons. First, it offers a direct, albeit old-fashioned, formalization of the notion we are after, namely that GE adjustment takes time. Second, it illustrates more generally how this notion can be captured by all the other variants that drop the REE concept: one must make the assumption that the “depth of reasoning” increases with the passage of time. With Level-k Thinking, for example, one has to assume that \( k \) increases with \( t \); and with Gabaix’s variant, one has to assume that \( \mu \), the cognitive discount factor, increases with \( t \). We now show how lack of common knowledge captures the same notion without either a departure from rational expectations or the need for any such additional assumption: the attenuation has to decrease with time, simply because rational agents extract information from realized outcomes.

Similarly to Section 6, we summarize the information that is available to marketplace \( m \) at the moment the shock hits (\( t = 0 \)) in a local signal \( s_m \) given by

\[
s_m = \Delta \overline{\theta} + v_m,
\]

where \( \Delta \overline{\theta} \) is the underlying shock and \( v_i \) is an idiosyncratic noise. term, drawn from \( N(0, \sigma_v^2) \), i.i.d. across marketplaces, and independent of \( \Delta \overline{\theta} \). Unlike our earlier analysis, however, we must now take into account the fact that the information structure changes endogenously over time, as agents relocate and trade.

In general, the task of characterizing the dynamics of beliefs in stationary settings with dispersed private information and endogenous learning can be rather daunting. For example, Huo and Takayama (2015) prove that an exact finite-
state-space solution is impossible for a large class of such settings. Here, the task is more manageable thanks to two key assumptions: that there is a single, once-and-for-all aggregate shock; and that the endogenous learning boils down to a bilateral exchange of the private information of any two marketplaces within any realized match.\textsuperscript{45}

Let us explain. Fix a period \( t \geq 1 \), a particular marketplace \( m \), and a particular realization of the aforementioned pairwise matching, and let \( m' \) denote the match of marketplace \( m \). At the moment its local markets for capital and labor open, marketplace \( m \) is populated by two types of agents: those that we previously located in \( m \) (the “locals”) and those that were previously located in \( m' \) (the “foreigners”). By observing the local prices \( p_{m,t} \) and/or \( w_{m,t} \), both type of agents can infer the local capital stock, \( k_{m,t} \). Recall that the latter is given by a weighted average of the investment made by the two type of agents, i.e., \( k_{m,t} = p k_{m,t-1} + (1 - \rho^2) k_{m',t-1} \). Furthermore, each type knows its own investment, i.e., the locals know \( k_{m,t-1} \) and the foreigners know \( k_{m',t-1} \). It follows that the observation of the local prices perfectly reveals \( k_{m,t-1} \) to the foreigners and \( k_{m',t-1} \) to the locals. Next, note that \( k_{m,t-1} = K(\theta_m, E_{m,t-1}[\bar{p}_t]) \) and \( k_{m',t-1} = K(\theta_{m'}, E_{m',t-1}[\bar{p}_t]) \), where \( K \) is a commonly known function. Furthermore, the foreigners directly observe \( \theta_m \) as soon as they arrive in marketplace \( m \). It follows that, by observing the local prices and learning \( k_{m,t-1} \), the foreigners also learn \( E_{m,t-1}[\bar{p}_t] \). To simplify the analysis, we assume the foreigners also tell the locals what \( \theta_{m'} \) was. It follows that, by learning \( k_{m',t-1} \), the locals learn \( E_{m',t-1}[\bar{p}_t] \). Furthermore, because there is no aggregate shock other than the one in the \( \theta \), the equilibrium \( \bar{p}_t \) is a known, albeit time-varying, function of \( \theta \). It follows that the local learn \( E_{m',t-1}[\bar{\theta}] \) and the foreigners learn \( E_{m,t-1}[\bar{\theta}] \). That is, it is as if the two types of agents exchange their (pre-trading) posterior beliefs about \( \bar{\theta} \).

We are thus able to show the following.

**Lemma 9.** There exists a deterministic sequence \( \{\lambda_t\}_{t=0}^{+\infty} \), with \( 0 < \lambda_t < \lambda_{t+1} < 1 \) \( \forall t \), such that the following is true:

(i) The belief hierarchy satisfies
\[
E^h_t[\bar{\theta}] = \bar{\theta}_{old} + \lambda^h_t \Delta \bar{\theta} \quad \forall t, h,
\]
where \( E^h_t[\cdot] \) denotes that \( h \)-th order average expectation operator in period \( t \).\textsuperscript{46}

(ii) The equilibrium expectations of the price of capital are given by
\[
E_t[\bar{p}_{t+1}] = \bar{p}_{old} + \pi(\lambda_t) (\bar{p}_{new} - \bar{p}_{old}) \quad \forall t,
\]
where the function \( \pi \) is continuous and strictly increasing in \( \lambda \), with \( \pi(0) = 0 \) and \( \pi(1) = 1 \).

(iii) \( \lambda_t \to 1 \) as \( t \to \infty \).

The characterization of sequence \( \{\lambda_t\}_{t=0}^{\infty} \) can be found in the Appendix. For the present purposes, it suffices to note that the lack of common knowledge diminishes over time and eventually vanishes. That is, for any given \( h \geq 1 \), the average \( h \)-th order belief of the aggregate fundamental moves monotonically from a value closer to \( \bar{\theta}_{old} \) to a value closer to \( \bar{\theta}_{new} \) as time passes. But the higher \( h \) is, the more anchored the \( h \)-th order belief is to \( \bar{\theta}_{old} \) and the more time it takes for it to cover any given distance between \( \bar{\theta}_{old} \) and \( \bar{\theta}_{new} \). And because the period-\( t \) equilibrium expectation of the price of capital can be expressed as a function of the contemporaneous belief hierarchy, we then obtain that this expectation itself converges monotonically from \( \bar{p}_{old} \) to \( \bar{p}_{new} \).

The following is then a direct implication.

**Proposition 12.** In the Tâtonnement variant described above, the dynamic response of aggregate investment to the aggregate shock is given by
\[
\bar{k}_t = \bar{k}_{old} + \left\{ e^{micro} + \pi(\lambda_t) (e^{Macro} - e^{micro}) \right\} \Delta \bar{\theta},
\]
where \( e \) is the same function as the one appearing in Lemma 9.

\textsuperscript{45}In this regard, our setting features a similar “information percolation” as Duffie and Manso (2007).

\textsuperscript{46}This is defined recursively by \( E^h_t[\cdot] \equiv \int E_{m,t} E^h_t[\cdot] dm + E^h_{t-1}[\cdot] dt \) for all \( h \geq 2 \).
This provides our preferred formalization of the notion that “GE adjustment takes times”: for \( t \) low enough, the change in \( \tilde{k}_t \) relative to the change in \( \tilde{\theta} \) is close to \( \epsilon^{micro} \); but as time passes, this change gets closer and closer to \( \epsilon^{Macro} \).

If we were free to choose any increasing sequence \( \{\lambda_t\}_{t=0}^{+\infty} \) in \((0,1)\), we could replicate exactly the dynamic response obtained in the variant with Tâtonnement dynamics and, more generally, we could rationalize any speed. For better or worse, we are not entirely free to choose this sequence: it \( \{\lambda_t\}_{t=0}^{+\infty} \) is dictated by the Bayesian learning that obtains endogenously given the assumed trading structure. That said, the essence is that lack of common knowledge rationalizes the patterns seen in Figure 4: because of the learning, the GE attenuation has to decrease with time.

What is more, the following variant of Proposition 6 applies.

**Proposition 13.** Fix the information structure and normalize \( \epsilon^{Macro} = 1 \). For any \( t \geq 0 \), \( \tilde{k}_t \) is further away from \( \tilde{k}_{new} \), the larger \( |\alpha| \). Hence, when the GE effect is larger, it takes more time for it to settle in.

This is an intriguing prediction, not shared by our Tâtonnement variant, but naturally implied from the combination of rational expectations with lack of common knowledge. In our setting, the information that every agent accumulates as time passes is invariant to \( \alpha \). This means that we can vary the strength of the GE effect while holding constant the sequence \( \{\lambda_t\}_{t=0}^{+\infty} \), which in turn gives the above result. In an extension that allows the agents to learn also from noisy signals of the aggregate outcome \( \tilde{k}_t \), one can show that the informativeness of these signals decreases with \( |\alpha| \). This reinforces the above message and offers an additional example of the predictive power of our preferred approach.

### 9 Lessons and Applications

In this section, we summarize the key lessons, compare the different methodological approaches under consideration, and discuss few applications.

#### 9.1 Main Lessons and Discussion

The results of our paper can be summarized as follows. The variants that are based on lack of common knowledge or Tâtonnement dynamics are able to capture the sought-after notion of GE attenuation regardless of whether the relevant GE effects amplify or offset the corresponding PE effects. By contrast, the variants that are based on Level-k Thinking and Cobweb dynamics have an inherent difficulty in capturing the sought-after notion of GE attenuation in settings in which the GE effects offset the PE effects. That said, we also showed how the reflective-equilibrium concept of Garcia-Schmidt and Woodford (2015) helps reconcile the essence of Level-k Thinking, if not its exact form, with the notion of GE attenuation. We finally discussed why the approach of Gabaix (2016) can also accommodate this notion.

From a big-picture perspective, the various approaches therefore appear to be close substitutes to one another. Accordingly, we would like to summarize the main take-home lesson of our paper as follows.

**Take-Home Lesson.** GE attenuation appears to be a robust implication of allowing either for plausible forms of bounded rationality, or for a realistic friction in the ability of the agents to reach common knowledge of the state of the economy and to coordinate their behavior.

That said, we also feel that, on the margin, there are good reasons to favor the approach that relaxes the common-knowledge requirements of standard models instead of dropping the rational-expectations hypothesis.

First of all, any departure from the REE concept is, by its very nature, subject to Lucas’ critique. Of course, this does not mean that one should be dogmatic about rational expectations. However, insofar as one assigns a positive value to interpretations of the data and to policy prescription that do not rest on the presumption that agents make repeated,
and systematic, mistakes, the balance is tilted in favor the approach that maintains the REE concept but relaxes the common-knowledge assumptions of the theory.

Second, this approach is more “disciplined” in the sense that it does not allow the possibility to obtain the opposite result. This contrasts ε-equilibrium, the approach taken in Gabaix (2016), and Level-k Thinking in contexts where the GE effects offset PE effects.

Third, once our preferred approach is adapted to multi-period settings (as we did in the last section), it makes a sharp prediction: the GE effects of any given aggregate shock are attenuated relative to their frictionless counterparts in the short run, but get closer and closer to the latter as the time passes. The reason is that the level of common knowledge about the underlying aggregate shock increases endogenously as the agents observe past market outcomes.

This prediction appears to be, not only a priori plausible, but also consistent with the evidence documented in Coibion and Gorodnichenko (2012). Yet, this prediction is not necessarily shared by the alternative approaches.

Consider the particular setting studied in the last section. A key feature of that setting was that a shock occurs only once, in the beginning of the calendar time. In such as setting, one can reconcile the idea that GE adjustment takes time with some of the considered forms of bounded rationality, such as Level-k Thinking, by making the additional assumption that agents become “deeper thinkers” as the calendar time increases. However, this begs the question of what justifies this assumption.

What is more, this assumption is not useful to stationary environments with recurring shocks. In such settings, one would need the depth of thinking to increase, not with calendar time, but rather with the time lag since the shock has occurred. But how could it be that agents are shallow thinkers vis-a-vis recent shocks and, at the same time, are deep thinkers vis-a-vis shocks that occurred further in the past?

Fourth, note that the approaches that drop the REE concept require the selection of a “default point” that serves as the anchor of the conjectures that the agents form about the actions of others or, equivalently, about all the endogenous economic outcomes. In the variants studied in 7, this default point was assumed to coincide with \( \bar{p}_{old} \) or \( \bar{q}_{old} \); the preshock frictionless outcomes.

This appears to mirror the specification of the common prior in Section 6: in the incomplete-information variant, the equilibrium beliefs of \( \bar{p} \) and \( \bar{q} \) were anchored to, respectively, \( \bar{p}_{old} \) and \( \bar{q}_{old} \) only because the common prior of the underlying aggregate fundamental was centered around \( \bar{\theta}_{old} \). Does this means that the two approaches have the same degree of freedom in choosing the relevant belief anchor?

Not really. Once our preferred approach is adapted to stationary dynamic settings, there is no such freedom: the objective probability distribution of the exogenous fundamentals together with Bayesian learning discipline what the anchor is. By contrast, with the non-REE alternatives, the default point remains a free parameter, which can be disciplined only with additional assumptions.  

Last but not least, it is not clear whether the REE concept is more demanding on the cognitive abilities of an agent than any of the considered forms of bounded rationality. Indeed, what is easier? To solve for the REE fixed point; to compute the \( k \)-th order iteration of the mapping \( T \) for \( k \geq 1 \); to solve the ODE associated with the reflective equilibrium; or to solve the modified fixed point proposed by Gabaix (2016)? In our view, the answer to this question is not obvious. We therefore think that the common appeal of all these approaches is their ability to generate predictions that seem conceptually plausible and empirically relevant, but are inconsistent with the frictionless benchmark.

To conclude, we feel that, on the margin, the balance is tilted in the direction of the methodological approach that maintains the rational-expectations solution concept but examines the robustness of its observable implications to lack of common knowledge of the underlying fundamentals—which is the approach taken in Section 6 of the present paper, in the complementary contributions of Morris and Shin (2001, 2003) and Bergemann and Morris (2013), and in most...
of the literature reviewed in Angeletos and Lian (2016b). However, we do not wish to disparage any of the bounded-rationality alternatives. To the contrary, we believe that both informational and cognitive frictions are realistic. We thus find it reassuring for the message of this paper that the two kinds of friction can complement each other in the direction of attenuating GE effects.

9.2 Applications

We now discuss a few possible applications, some of which we explore in companion work. These applications cannot be nested in the abstract framework of this paper: they feature micro-foundations that are appropriate for the particular contexts of interest, richer market structures, more elaborate forms of forward-looking behavior, and specific kinds of PE and GE effects. They nevertheless share the central theme of this paper, namely the attenuation of GE mechanisms.

To illustrate, consider Angeletos and Lian (2016a). In that paper, we show how relaxing the common-knowledge requirements of an otherwise standard New-Keynesian model attenuates the GE effects of monetary policy and lessens the “forward guidance puzzle”. In the next few paragraphs, we briefly review the puzzle, the contribution of our companion paper, and its relation to the present paper.

The aforementioned puzzle refers to the following issue. Suppose the economy is described by the New-Keynesian model. Suppose further that the economy is in a slump and that the zero-lower-bound (ZLB) binds up to a future date $t = T - 1$, for some $T \geq 2$. Because of this constraint, the monetary authority is unable to stimulate aggregate demand by reducing the current Federal funds rate. Yet, according to the model, the same goal can be achieved by a credible promise to keep the interest rate below its “natural level” after the ZLB has ceased to bind, that is, at $t \geq T$. For plausible parameterizations of the model, the effectiveness of such a policy is quantitatively large. What is more, for any parameterization, the effectiveness increases with $T$: the further into the future forward guidance has to operate, the stronger its impact on current economic activity and inflation. Last but not least, a greater degree of price flexibility implies a greater degree of monetary non-neutrality, as measured by the elasticity of current activity to the interest rate set after the ZLB has ceased to bind.

These predictions are considered, by many economists, as empirically implausible, which is why the issue is known as a “puzzle”. For our purposes, the key is to observe that these predictions are driven by certain GE effects. The most crucial among these GE effects is the feedback loop between aggregate spending and inflation. Reducing the nominal interest rate at $t = T$ causes inflation at $t = T$. Because the nominal interest rate is pegged at zero prior to $T$, the increase in inflation translates to a low real interest rate between $T - 1$ and $T$. This stimulates aggregate spending at $T - 1$, contributing to even higher inflation at $T - 1$, which in turn feeds to even higher spending at $T - 2$, and so on. Clearly, the cumulative effect at $t = 0$ increases with $T$, which explains why the power of forward guidance also increases with $T$. Finally, by permitting a greater inflation response, a greater degree of price flexibility increases the potency of this GE mechanism, thus also increasing the effectiveness of monetary policy.

In the standard New-Keynesian model, the aforementioned GE mechanism is captured by the interaction of the representative household’s Euler condition with the New-Keynesian Philips Curve (NKPC). But there are two additional GE mechanisms, buried underneath these equations. The one has to do with the feedback from future inflation to current inflation: for given real marginal costs, the individual firm is more willing to raise its nominal price today if she expects other firms to do the same in the future. The other has to do with the feedback from aggregate spending to individual spending: when the individual consumer expects other consumers to spend more, she is encouraged to spend more herself, because her own income increases with aggregate consumption.

Our main result in Angeletos and Lian (2016a) is that removing common knowledge of the policy attenuates all the aforementioned GE effects and, in so doing, reduces the ability of the policy maker to stimulate the economy. This result can be seen as a concrete application of the broader ideas formalized in the present paper. Nevertheless, it is
worth highlighting three subtleties.

First, the framework used in that paper does not feature the kind of market segmentation assumed in the present paper: markets are centralized. The desired friction—lack of common knowledge—is then preserved by allowing for enough sources of uncertainty so that the observed prices are not perfectly revealing. This underscores that, although the particular market structure assumed in the present paper permitted a particular specification of the “geography” of information, these particulars are not strictly needed for our insights to apply.

Second, the GE effects featured in that paper have a much richer dynamic structure than those featured in the present paper. This is because the optimal consumption of an individual household in any given period depends on the income and the interest rate she expects to face in all future periods—and similarly the optimal reset price of a firm depends on the inflation and the real marginal costs she expects to face in all future periods. To make an analogy, think of each future period in that paper as a different kind of “afternoon markets” in the present paper, with price of each such market entering the demand and supply in the “morning market”. Despite this complexity, a sharp characterization is possible thanks to the fact that all the relevant GE effects work in the same direction.

Last but not least, because of the aforementioned forward-looking aspects, a new, and context-specific, prediction emerges: the documented attenuation is stronger the further into the future the policy operates (i.e., the larger $T$ is). This is because longer horizons maps to beliefs of higher order, which are themselves more anchored to the common prior for any given level of informational friction.

Additional applications include Angeletos and Lian (2017) and Angeletos and Lian (2016c). In the former paper, we explore how lack of common knowledge affects the validity of Ricardian Equivalence and the macroeconomic effects of shocks to taxes and government spending in both the RBC and the New-Keynesian framework. In the latter paper, we shift attention to the popular notion—if not the apparent fact—that a drop in consumer spending, such as the one triggered by a “discount-factor shock” or by deleveraging, can trigger a recession. As noted in the Introduction, this notion is grounded on solid PE intuitions, yet it finds no place in the RBC framework because of countervailing GE effects. In our companion paper, we add an information friction that, not only helps attenuate these GE effects along the lines suggested by the present paper, but also introduces a feedback mechanism that resembles the Keynesian multiplier, despite the absence of nominal rigidity. As a result, the modified RBC model is able, not only to accommodate the aforementioned notion/fact, but also to disentangle the degree of monetary non-neutrality from the question of whether and how “demand forces” explain the observed business cycles.48

Finally, the works of Angeletos and La'O (2010), Venkateswaran (2014), and Schaal and Taschereau-Dumouchel (2015) can also be understood as applications of the broader theme of our paper. The first paper effectively attenuates the GE effects of TFP shocks in the RBC model and argues that this helps reconcile that model with the evidence in Gali (1999). The second paper effectively attenuates the GE effects of TFP shocks in the DMP model and argues that this helps lessen the “Shimer puzzle” (Shimer, 2005). The third paper effectively attenuates the GE interaction of the firms in a variant of the RBC model with non-convex technologies. When TFP shocks are common knowledge, this interaction is strong enough that multiple equilibria are possible; when instead there is sufficient higher-order uncertainty about the underlying TFP shocks, this interaction gets weakened enough that a unique equilibrium is selected.

We hope that these applications indicate, not only the broad applicability of the insights and of the perspective developed in this paper, but also the added value of exploring specific applications: such applications can deliver concrete empirical predictions and useful policy lessons, which are not possible in the present paper due to the assumed level of abstraction.

48This does not mean that we favor models that feature monetary neutrality. We only wish to contrast with the New-Keynesian framework, which prohibits the aforementioned kind of disentangling.
10 Conclusion

General-equilibrium effects that operate at the economy-wide level are central to understanding the response of macroeconomic outcomes to aggregate shocks, as well as to policy interventions. Such effects limit the usefulness of partial-equilibrium intuitions. They also introduce a gap between the macroeconomic effects of interest and the kind of micro or local elasticities that are estimated in a growing empirical literature.

In this paper, we sought to operationalize the notion that general-equilibrium effects may be less potent, or may take more time to build force, than what is often presumed in applied research. To this goal, we built on existing insights from various strands of the literature, but also blended them in a new—and hopefully insightful—manner.

We considered an elementary Walrasian economy, in which trading was sequential and decentralized. We fixed the microeconomic foundations in terms of the specification of preferences, technologies, and market structures; in so doing, we also fixed the relevant demand and supply functions. We next characterized the response of this economy to an aggregate shock under a benchmark specification that, in line with the vast majority of applied work, imposed rational expectations along with common knowledge of the aggregate shock. We then departed from that benchmark in two distinct ways. In the one, we dropped the rational-expectations solution concept in favor of certain kinds of bounded rationality. In the other, we maintained the rational-expectations solution concept but removed common knowledge of the aggregate shocks. We explored the similarities and the differences of the two approaches and concluded that, although both approaches can help accommodate the sought-after notion, the latter approach appears to do so in a more natural and more structured manner.

Our framework was deliberately simple and abstract. The intended goals were to simplify the analysis and to deliver the key insights in a transparent and flexible manner. The obvious cost is that the assumed level of abstraction prevented any concrete application. We thus view the contribution of the present paper as a “proof of concept” and explore a few applications in companion work (Angeletos and Lian, 2016a,c, 2017). In these applications, we adopt the approach that maintains rational expectations but allows for incomplete information. As explained here, the alternatives considered in García-Schmidt and Woodford (2015), Gabaix (2016), and Farhi and Werning (2017) are highly complementary, even though they do not share the exact same restrictions as our preferred approach.

All in all, we hope that our paper has shed new light on the sensitivity of the predictions of general-equilibrium models to plausible relaxations of either the rational-expectations solution concept or the conventional but unrealistic assumption that all agents share the same beliefs about the current state and the future prospects of the economy. Perhaps there is more to “simplistic” partial-equilibrium intuitions than the general-equilibrium theorist is trained to see. Perhaps the macroeconomist should question how much her favorite structural interpretation of the business cycle depends on general-equilibrium mechanisms that are sensitive in the respects we have highlighted in this paper. And perhaps the policy maker should put more emphasis on policies that work through salient PE effects, as opposed to multi-layer GE effects, if she wishes to steer the economy in the short run.49

49The last point is related to the rationale we provide in our companion work for “front loading” fiscal and monetary policy.
Appendix A. Connection to Empirical Work

Recently, there has been a boom of empirical research trying to gauge the macroeconomic effects of aggregate shocks by exploiting the cross-sectional heterogeneity in the exposure of different geographical regions to these shocks. Important examples include Mian and Sufi (2012, 2014) and Beraja, Hurst, and Ospina (2016) in the context of the Great Recession, and Nakamura and Steinsson (2014) in the context of fiscal multipliers. At the risk of overreaching, we briefly discuss how our analysis can be connected to this line of empirical work.

The type of empirical exercises conducted in these works can be represented in our baseline framework as follows. Suppose that the data contain observations of $\Delta \theta$, the aggregate shock of interest, and of $\Delta q$, the corresponding change in the outcome of interest. Suppose further that, apart from the shock of interest, there are other shocks that are neither of interest to, nor observed by, the econometrician. It follows that

$$\Delta q = \varepsilon^{Macro} \Delta \theta + \varepsilon,$$

where $\varepsilon^{Macro}$ is the macro elasticity of interest and $\varepsilon$ is residual that captures the other shocks.

Clearly, an unbiased estimate of $\varepsilon^{Macro}$ can be extracted from aggregate times series only if $\varepsilon$ is uncorrelated with $\Delta \theta$ or the econometrician has an instrument for $\Delta \theta$ that is itself uncorrelated with $\varepsilon$. In practice, these conditions are rarely met. To overcome this limitation, the aforementioned works shift focus to the cross section and offer a credible instrument for the differential exposure of different regions to the shock. There is, however, an important caveat: what is actually estimated is a certain kind of micro elasticity, rather than the macro elasticity of interest.

To see this more clearly, suppose that a marketplace in the theory corresponds to a region in the data (say, a ZIP code or a metropolitan area). The change in the regional outcome of interest can then be expressed as follows:

$$\Delta q_m = \frac{\partial Q}{\partial \theta} (\delta_m \Delta \theta + z_m) + \frac{\partial Q}{\partial p} \frac{\partial P}{\partial \theta} \Delta \theta + (\varepsilon + \xi_m),$$

where $\varepsilon$ and $\xi_m$ capture, respectively, the aggregate and the idiosyncratic effects of the other, unobserved, shocks. Using the facts that $\frac{\partial Q}{\partial \theta} = PE = \varepsilon^{micro}$ and $\frac{\partial Q}{\partial p} \frac{\partial P}{\partial \theta} = GE = \varepsilon^{Macro} - \varepsilon^{micro}$, we can restate the above as

$$\Delta q_m = \varepsilon^{micro} \delta_m \Delta \theta + \eta + v_m,$$

where

$$\eta \equiv \varepsilon + (\varepsilon^{Macro} - \varepsilon^{micro}) \Delta \theta \quad \text{and} \quad v_m \equiv \xi_m + \varepsilon^{micro} z_m.$$

Since $\eta$ is common to all regions, it is subsumed by the constant of a cross-sectional regression or, if we have longer data, by the time-fixed effect of a panel regression. Having a credible instrument for the differential exposure to the aggregate shock of interest means that, once the time-fixed effect has been partial out, the available instrument covaries with $\delta_m \Delta \theta$ but not with the residual $v_m$. This permits the econometrician to obtain an unbiased estimate of $\varepsilon^{micro}$, which is valuable—but unless the gap between $\varepsilon^{Macro}$ and $\varepsilon^{micro}$ happens to be small, this estimate gives little information about ultimate object of interest, namely about the macroeconomic effect of $\Delta \theta$.

This epitomizes the conundrum faced by the aforementioned line of empirical work: allowing for a time fixed effect in the relevant regressions partials out, not only the concurrent shocks that contaminate the aggregate time series, but also the GE effects of the shock of interest. In this paper, we provide a potential resolution to this conundrum: by offering a rationale for why at least some of these GE effect may be impotent in the short run, we reduce the gap between the object that is of interest and the one that is actually estimated in the aforementioned works.

---

50For the purposes of the present discussion, one can think of the econometrician observing $\theta$ and $q$ at multiple points of time, each of which correspond to a different morning in an appropriate multi-period version of our framework. See Section 8 for such an extension.
Remark 1. The above discussion has assumed that a “marketplace” in our theory coincides with a “region” in the data (that is, with the relevant level of observation in the available cross-sectional data). In the absence of such a coincidence, the mapping between the theory and the data is more nuanced. However, provided that any two agents who live in the same region are more likely to participate in the same markets than any two agents from different regions, we expect the essence of the conveyed message to survive.

Remark 2. The above discussion has also assumed that the micro elasticity is the same across all regions. In empirical work, this assumption is often relaxed. Our point remains valid provided that one reinterprets $\epsilon_{\text{micro}}$ as the appropriate cross-sectional average of the regional elasticities.

Remark 3. The aforementioned empirical literature often emphasizes differential effects of the same shock on different kinds of economic outcomes, such as employment in tradable versus non-tradable sectors in the case of Mian and Sufi (2014). The points made above apply regardless: for each of the considered outcomes, the aforementioned work estimates, at best, a local elasticity.

Appendix B. Proofs

Proof of Lemma 1. Consider a firm $i$ that trades in markets $m$ and $m'$ in, respectively, the morning and the afternoon. Because the technology is convex, the following conditions are necessary and sufficient for optimality:

$$\hat{E}_m \left[ \frac{\partial \Gamma}{\partial q} (q_i, q_i^*; \theta_m) \right] = p_m,$$  
$$\frac{\partial \Gamma^*}{\partial q^*} (q_i, q_i^*; \theta_m) = p_{m'},$$

where $\hat{E}_m [\cdot]$ denotes subjective—potentially irrational—belief of agents who trade in market $m$ in the morning (By Assumption 2, agents in the same market share the same belief in the morning).

Now, consider the optimal behavior of a household $i$ that trades in markets $m$ and $m'$ in, respectively, the morning and the afternoon. It is pinned down by the solution to the following first-order conditions together with the budget constraint (3):

$$\hat{E}_m \left[ \frac{\partial U}{\partial c} (c_i, c_i^*; \theta_m) \right] = p_m,$$  
$$\frac{\partial U}{\partial c^*} (q_i, q_i^*; \theta_m) = p_{m'},$$

As in the main text, we henceforth re-interpret all the variables as log-deviations from a symmetric steady state (in which all marketplaces have the same fundamentals) and work with the log-linearized demand and supply system.

Solving and (log-linearizing) conditions (50) and (52), we can find linear functions $D^*$ and $S^*$ such that

$$c_i^* = D^* (c_i, p_{m'}, \theta_m) \quad \text{and} \quad q_i^* = S^* (q_i, p_{m'}, \theta_m).$$

By individual rationality, we can then substitute the previous condition into conditions (49) and (51). We can find linear functions $D$ and $S$ such that

$$c_m = c_i = D \left( p_m, \hat{E}_m [p_{m'}^*], \theta_m \right) \quad \text{and} \quad q_m = q_i = S \left( p_m, \hat{E}_m [p_{m'}^*], \theta_m \right),$$

where we use the fact that consumers (firms) of any given marketplace $m$ are identical in the morning.

Now let us consider the demand and supply in any afternoon market $m$. Note that the demand in afternoon market $m$ has two components: one reflecting the agents who were in this market from the morning; and another reflecting the
agents who were relocated from other markets. The former have mass \( \rho \) and their demand is given by \( D^* (c_m, p^*_m, \theta_m) \); the latter have mass \( 1 - \rho \) and their average demand is given \( \int D^* (c_m', p^*_m, \theta_m) \, dm' = D^* (\bar{c}, p^*_m, \bar{\theta}) \). As a result,

\[
    c^*_m = \rho D^* (c_m, p^*_m, \theta_m) + (1 - \rho) D^* (\bar{c}, p^*_m, \bar{\theta}) .
\]

The same logic applies on the supply side.

**Proof of Lemma 2.** From the main text, we know the average market clearing price, \( \bar{p}^* \), in the afternoon is given by \( \bar{p}^* = P^* (\bar{q}, \bar{\theta}) \). The quantity of afternoon goods is then given by

\[
    \bar{q}^* = \int \{ \rho D^* (q_m, p^*_m, \theta_m) + (1 - \rho) D^* (\bar{q}, p^*_m, \bar{q}) \} \, dm = D^* (\bar{q}, \bar{p}^*, \bar{\theta}) = Q^* (\bar{q}, \bar{\theta})
\]

where \( Q^* (\bar{q}, \bar{\theta}) = D^* (\bar{q}, P^* (\bar{q}, \bar{\theta}), \bar{\theta}) \) for all \( (\bar{q}, \bar{\theta}) \).

Now we consider the afternoon outcome. Pick a particular marketplace \( m \) and let \( p^*_m = \rho P^* (q_m, \theta_m) + (1 - \rho) \bar{p}^* \). Because \( N^* \) is linear, from condition (6) we have

\[
    n^*_m = N^* (\rho q_m + (1 - \rho) \bar{q} = \rho P^* (q_m, \theta_m) + (1 - \rho) \bar{p}^* , \rho \theta_m + (1 - \rho) \bar{\theta} ) .
\]

\[
    = \rho N^* (q_m, P^* (q_m, \theta_m), \theta_m) + (1 - \rho) N^* (\bar{q}, \bar{p}^*, \bar{\theta})
\]

\[
    = 0
\]

which means that the aforementioned value for \( p^*_m \) clears the afternoon market. Because \( N^*(\cdot, p^*, \cdot) \) is decreasing in \( p^* \), the aforementioned value for \( p^*_m \) is the unique market-clearing price. The corresponding quantity is then given by

\[
    q^*_m = \rho D^* (q^*_m, p^*_m, \theta_m) + (1 - \rho) D^* (\bar{q}, \bar{p}^*, \bar{\theta})
\]

\[
    = \rho D^* (q_m, P^* (q_m, \theta_m), \theta_m) + (1 - \rho) D^* (\bar{q}, P^* (\bar{q}, \bar{\theta}), \bar{\theta})
\]

\[
    = \rho Q^* (q_m, \theta_m) + (1 - \rho) Q^* (\bar{q}, \bar{p}^*) ,
\]

where \( Q^* \) is defined as before.

**Proof of Lemma 3.** Using conditions (11), (9) and the linearity of \( \hat{Q} \), we have

\[
    q_m = \rho^2 \hat{Q} (P^* (q_m, \theta_m), \theta_m) + (1 - \rho^2) \hat{Q} (\hat{E}_m [\bar{p}^*], \theta_m) .
\]

Suppose \( \rho^2 \hat{\alpha} = \rho^2 \frac{\partial P^*}{\partial q} \frac{\partial \hat{Q}}{\partial p} \neq 1 \). The above then has a unique solution in \( q_m \), given by

\[
    q_m = Q (\hat{E}_m [\bar{p}^*], \theta_m) ,
\]

where \( Q \) is a linear function defined implicitly so that, for all \( (p^*, \theta) \),

\[
    Q (p^*, \theta) = \rho^2 \hat{Q} (P^* (Q (p^*, \theta), \theta), \theta) + (1 - \rho^2) \hat{Q} (p^*, \theta) .
\]
Similarly, using condition (11), (9) and the linearity of $\tilde{P}$, we have

$$
\begin{align*}
p_m &= \tilde{P} \left( \rho^2 P^* (q_m, \theta_m) + (1 - \rho^2) \hat{E}_m [\tilde{p}^*], \theta_m \right) \\
&= \tilde{P} \left( \rho^2 P^* \left( Q(\hat{E}_m [\tilde{p}^*], \theta_m), \theta_m \right) + (1 - \rho^2) \hat{E}_m [\tilde{p}^*], \theta_m \right) \\
&= P \left( \hat{E}_m [\tilde{p}^*], \theta_m \right).
\end{align*}
$$

(54)

By aggregation, we then have

$$
\tilde{q} = Q \left( \int \hat{E}_m [\tilde{p}^*] \, dm, \tilde{\theta} \right) \quad \text{and} \quad \tilde{p} = P \left( \int \hat{E}_m [\tilde{p}^*] \, dm, \tilde{\theta} \right).
$$

From Assumption 4, agents in the economy can do the above reasoning. As a result, Lemmas 2 (in particular functions $(Q, P, Q^*, P^*)$) and 3 are known to the agents.

**Proof of Proposition 1.** Let me first prove condition (15) in the main text. First, as $T(p^*, \theta) \equiv P^* (Q(p^*, \theta), \theta)$ for all $(p^*, \theta)$, we have

$$
\frac{\partial T}{\partial p^*} = \frac{\partial P^*}{\partial q} \frac{\partial Q}{\partial p^*}.
$$

(55)

From the definition of $Q$ in condition (53), we have

$$
\frac{\partial Q}{\partial p^*} = \frac{1 - \rho^2}{1 - \alpha \rho^2} \frac{\partial \tilde{Q}}{\partial p^*}.
$$

(56)

Together with condition (55), we have

$$
\frac{\partial T}{\partial p^*} = \frac{1 - \rho^2}{1 - \alpha \rho^2} \frac{\partial P^*}{\partial q} \frac{\partial \tilde{Q}}{\partial p^*} = \frac{1 - \rho^2}{1 - \alpha \rho^2} \tilde{\alpha}.
$$

This finishes the proof of condition (15) in the main text. Together with Assumption 5 and the fact $\rho \in [0, 1)$, we have

$$
-1 < \alpha = \frac{1 - \rho^2}{1 - \alpha \rho^2} \tilde{\alpha} < 1.
$$

As a result, $T$ is a contraction mapping. The unique solution of condition (14) can then be represented as

$$
E[\tilde{p}^*] = \mathcal{P}(\tilde{\theta}),
$$

where $\mathcal{P}(\theta)$ is a linear function such that $\mathcal{P}(\theta) = T(\mathcal{P}(\theta), \theta)$ for all $\theta$. This finishes the proof of part (i) of the Proposition. Part (ii) can be then derived from Lemmas 2 and 3.

**Proof of Proposition 2.** Use condition (17) and consider the change relative to its pre-shock value, we have

$$
\Delta q_m = Q \left( \mathcal{P} \left( \Delta \tilde{\theta} \right), \Delta \theta_m \right),
$$

(57)

$$
\Delta \tilde{q} = Q \left( \mathcal{P} \left( \Delta \tilde{\theta} \right), \Delta \tilde{\theta} \right) \equiv \epsilon_{\text{Macro}} \Delta \tilde{\theta},
$$

(58)

where

$$
\epsilon_{\text{Macro}} = \frac{\partial Q}{\partial \tilde{\theta}} + \frac{\partial Q}{\partial p^*} \frac{\partial \mathcal{P}}{\partial \tilde{\theta}}.
$$

(59)

Subtracting condition (58) from condition (57), we have
\[ \Delta q_m = \Delta \tilde{q} + \epsilon_{\text{micro}} (\Delta \tilde{\theta}_m - \Delta \tilde{\theta}) , \]

where \[ \epsilon_{\text{micro}} = \frac{\partial Q}{\partial \theta} . \] (60)

Proof of Corollary 1. The Proposition follows from conditions (59) and (60), and the fact that \( \int \delta_m dm = 1 \).

Proof of Lemma 4. Let us prove first that \( \mathcal{N}(p^*, \cdot) \) is decreasing in \( p^* \). First, by definition of \( \mathcal{N} \), we have \[ \frac{\partial \mathcal{N}}{\partial p^*} = \frac{1}{1 - \alpha p^2} \frac{\partial \mathcal{N}}{\partial \tilde{q}} + \frac{\partial \mathcal{N}}{\partial p^*} . \] Then, by condition (56), we have \[ \frac{\partial \mathcal{N}}{\partial p^*} = \frac{1}{1 - \alpha p^2} \frac{\partial \mathcal{N}}{\partial \tilde{q}} (1 - \alpha) < 0 . \] This proves that \( \mathcal{N}(p^*, \cdot) \) is decreasing in \( p^* \).

Now we turn to the proof of Lemma 4. Note that \[ \mathcal{N} \left( \hat{P}^*(t), \tilde{\theta}_{\text{new}} \right) = \mathcal{N} \left( \hat{P}^*(t), \tilde{\theta}_{\text{new}} \right) - \mathcal{N} \left( \bar{p}_{\text{new}}^*, \tilde{\theta}_{\text{new}} \right) = \frac{\partial \mathcal{N}}{\partial p^*} \left( \hat{P}^*(t) - \bar{p}_{\text{new}}^* \right) . \] From condition (18), we have \[ \frac{d \left( \hat{P}^*(t) - \bar{p}_{\text{old}}^* \right)}{dt} = \frac{\partial \mathcal{N}}{\partial p^*} \left( \left( \hat{P}^*(t) - \bar{p}_{\text{old}}^* \right) - \left( \bar{p}_{\text{new}}^* - \bar{p}_{\text{old}}^* \right) \right) \forall t \geq 0 . \]

Together with \( \hat{P}^*(0) = \bar{p}_{\text{old}}^* \), we have
\[ \hat{P}^*(t) - \bar{p}_{\text{old}}^* = \left( \bar{p}_{\text{new}}^* - \bar{p}_{\text{old}}^* \right) \left( 1 - e^{\frac{\partial \mathcal{N}}{\partial p^*} t} \right) . \] As a result,
\[ w(T) = 1 - e^{\frac{\partial \mathcal{N}}{\partial p^*} T} . \] (62)

Therefore, \( w(T) \) is continuous strictly increasing in \( T \), \( w(0) = 0 \) and \( \lim_{T \to \infty} w(T) = 1 \).

Proof of Proposition 3. The Proposition follows directly from condition (21), Lemma 4, and the fact that \( \epsilon_{\text{micro}} = \frac{\partial Q}{\partial \theta} \) and \( \epsilon_{\text{macro}} - \epsilon_{\text{micro}} = \frac{\partial Q}{\partial \theta} + \frac{\partial P}{\partial p} \).

Proof of Lemma 5. The Lemma follows directly from taking average expectations of both sides of condition (28).

Proof of Corollary 2. Iterating condition (28), we have
\[ \bar{p}^* = \frac{\partial T}{\partial \theta} \sum_{h=1}^{\infty} \left( \frac{\partial T}{\partial p^*} \right)^{h-1} E^h [\tilde{\theta}] , \] (63)
where for notational simplicity we let $E^0 [\bar{\theta}] = \bar{\theta}$. By condition (15), we have $\alpha = \frac{\partial T}{\partial p^*}$.

Using condition (16) and taking derivatives with respect to $\bar{\theta}$ in condition (14), we have

$$\gamma = \frac{\partial P}{\partial \bar{\theta}} = \frac{\partial T}{\partial \bar{\theta}} \frac{1}{1 - \alpha}.$$ (64)

Substituting into condition 63, we have

$$\bar{p}^* = \gamma (1 - \alpha) \sum_{h=1}^{\infty} \alpha^{h-1} E^{h-1} [\bar{\theta}].$$

Taking average expectation of $\bar{p}^*$ based on the previous expression, Corollary 2 is then proved.

**Proof of Lemma 6.** Substituting condition (24) into condition (2), we have

$$E [\bar{p}^*] = \gamma \bar{\theta}_{old} + \frac{\gamma (1 - \alpha) \lambda}{1 - \alpha \lambda} \Delta \bar{\theta} = \bar{p}^*_{old} + \pi(\lambda) (\bar{p}^*_\text{new} - \bar{p}^*_{old}),$$

where

$$\pi(\lambda) = \frac{(1 - \alpha) \lambda}{1 - \alpha \lambda}.$$ (65)

For $-1 < \alpha < 1$, $\pi$ is continuous and strictly increasing in $\lambda$, with $\pi(0) = 0$ and $\pi(1) = 1$.

**Proof of Proposition 4.** The result follows directly from condition (26) and Lemma 6.

**Proof of Corollary 3.** To prove part (i), note that for any $T \in (0, \infty)$, there exists a unique $\lambda \in (0, 1)$ such that $w(T) = \pi(\lambda)$. This is because (i) $w$ is continuous and strictly increasing in $T$, with $w(0) = 0$ and $\lim_{T \to \infty} w(T) = 1$ and (ii) $\pi$ is continuous and strictly increasing in $\lambda$, with $\pi(0) = 0$ and $\pi(1) = 1$. The Corollary then directly follows conditions (19), (22), (31) and (32).

To prove part (ii), similarly, note that for any $\lambda \in (0, 1)$, there exists a unique $T \in (0, \infty)$ such that $\pi(\lambda) = w(T)$. The Corollary then directly follows conditions (19), (22), (31) and (32).

**Proof of Proposition 5.** Substituting condition (27) into condition (25), we have

$$q_m = BR(\theta_m, E_m[\theta], E_m[\bar{\theta}]),$$

where

$$BR(\theta_m, \theta, q) = Q(P^*(q, \theta), \theta_m) \forall (\theta_m, \theta, q).$$

This proves part (i) of the Proposition.

Taking partial derivatives with respect to $q$ in the above condition, together with condition (55), we have

$$\frac{\partial BR}{\partial q} = \frac{\partial P^*}{\partial q} \frac{\partial Q}{\partial p^*} = \frac{\partial T}{\partial p^*} = \alpha.$$\text{This proves part (iii) of the Proposition.}
\( p^* = P^*(\bar{q}, \bar{\theta}) = P^*(Q(\bar{E}[p^*], \bar{\theta}), \bar{\theta}) = T(\bar{E}[p^*], \bar{\theta}). \)

Conversely, if \( \bar{p}^* = T(\bar{E}[\bar{p}^*], \bar{\theta}) \) and \( \bar{q} = Q(\bar{E}[\bar{p}^*], \bar{\theta}), \) we have

\[
P^*(\bar{q}, \bar{\theta}) = P^*(Q(\bar{E}[\bar{p}^*], \bar{\theta}), \bar{\theta}) = T(\bar{E}[\bar{p}^*], \bar{\theta}) = \bar{p}^*.
\]

As a result,

\[
P^*(\bar{E}[\bar{q}], \bar{E}[\bar{\theta}]) = \bar{E}[\bar{p}^*].
\]

Finally, from \( \bar{q} = Q(\bar{E}[\bar{p}^*], \bar{\theta}), \) we have

\[
\bar{q} = Q(P^*(\bar{E}[\bar{q}], \bar{E}[\bar{\theta}]), \bar{\theta}) = BR(\bar{\theta}, \bar{E}[\bar{\theta}], \bar{E}[\bar{q}]).
\]

This finishes the proof.

**Proof of Proposition 6.** From conditions (32) and (34), we have

\[
\epsilon_{\text{Macro}} \epsilon_{\text{Micro}} = \frac{1}{1 - \alpha},
\]

\[
\epsilon_{\text{Inc}} \epsilon_{\text{Macro}} = \frac{\pi(\lambda) \frac{\alpha}{1 - \alpha} \epsilon_{\text{Micro}}}{1 - \alpha \epsilon_{\text{Micro}}} = \frac{1 + \pi(\lambda) \frac{\alpha}{1 - \alpha}}{1 - \alpha \epsilon_{\text{Micro}}} = (1 - \alpha) + \frac{(1 - \alpha) \alpha \lambda}{1 - \alpha \lambda} = 1 - \alpha.
\]

The result is then immediate.

**Proof of Lemma 7.** Because \( T^0(\bar{p}^*_{\text{old}}, \bar{\theta}_{\text{new}}) = \bar{p}^*_{\text{old}}, \) we have \( g_0 = 0. \) Now proceed by induction. Suppose for \( k \geq 0, \) we have \( \bar{p}^* = \bar{p}^*_{\text{old}} + g_k (\bar{p}^*_{\text{new}} - \bar{p}^*_{\text{old}}). \) We have

\[
\bar{p}^*_{k+1} = T^{k+1}(\bar{p}^*_{\text{old}}, \bar{\theta}_{\text{new}})
\]

\[
= T(\bar{p}^*_{k}, \bar{\theta}_{\text{new}})
\]

\[
= \bar{p}^*_{\text{old}} + \frac{\partial T}{\partial p} g_k (\bar{p}^*_{\text{new}} - \bar{p}^*_{\text{old}}) + \frac{\partial T}{\partial \theta} (\bar{\theta}_{\text{new}} - \bar{\theta}_{\text{old}})
\]

\[
= \bar{p}^*_{\text{old}} + (\alpha g_k + (1 - \alpha)) (\bar{p}^*_{\text{new}} - \bar{p}^*_{\text{old}}),
\]

where the last equation uses the fact that

\[
\bar{p}^*_{\text{new}} - \bar{p}^*_{\text{old}} = \frac{\partial \mathcal{P}}{\partial \bar{\theta}} (\bar{\theta}_{\text{new}} - \bar{\theta}_{\text{old}}) = \frac{\partial T}{\partial \bar{\theta}} \frac{1 - \alpha}{1 - \alpha} (\bar{\theta}_{\text{new}} - \bar{\theta}_{\text{old}}),
\]

according to condition (64). As a result, we have

\[
\bar{p}^*_{k+1} = \bar{p}^*_{\text{old}} + g_{k+1} (\bar{p}^*_{\text{new}} - \bar{p}^*_{\text{old}}),
\]

where

\[
g_{k+1} = \alpha g_k + (1 - \alpha).
\]

This proves part (i) in the Lemma 7.
From condition (67) and the fact that $g_0 = 0$, we have, for all $k \geq 0$,

$$g_k = (1 - \alpha) \left( \frac{1 - \alpha^k}{1 - \alpha} \right) = 1 - \alpha^k. \quad (68)$$

From this formula, it is easy to see that $\lim_{k \to \infty} g_k = 1$. Moreover, if $\alpha > 0$, the sequence is strictly increasing and bounded between 0 and 1. Finally, if instead $\alpha < 0$, this sequence is non-monotone, with $g_k < 1$ whenever $k$ is even and $g_k > 1$ whenever $k$ is odd.

**Proof of Proposition 7.** From part (i) of Definition 3, we have

$$q_m = Q \left( \tilde{p}^*, \theta_m \right) \quad \text{and} \quad \bar{q} = P \left( \tilde{p}^*, \bar{\theta} \right).$$

Then, this proposition follows directly from Lemma 7.

**Proof of Proposition 8.** From part (ii) of the Definition 4, we have, for all $k \geq 0$,

$$q_m = Q \left( \tilde{E}_m[\tilde{p}^*], \theta_m \right) \quad \text{and} \quad \bar{q} = P \left( \tilde{E}_m[\tilde{p}^*], \bar{\theta} \right),$$

where $\tilde{E}_m[\tilde{p}^*] = P^*(B\mathcal{R}^k(\tilde{\theta}_{new}, \tilde{\theta}_{old}, \tilde{\theta}_{new})) = P^*(\hat{q}_k, \tilde{\theta}_{new})$. Note that, for $k \geq 1$, we have

$$P^*(\hat{q}_k, \tilde{\theta}_{new}) = P^*(B\mathcal{R} \left( \tilde{\theta}_{new}, \tilde{\theta}_{new}, \hat{q}_{k-1} \right), \tilde{\theta}_{new})$$

$$= P^*(Q \left( P^*(\hat{q}_{k-1}, \tilde{\theta}_{new}), \tilde{\theta}_{new} \right), \tilde{\theta}_{new})$$

$$= T(P^*(\hat{q}_{k-1}, \tilde{\theta}_{new}), \tilde{\theta}_{new})$$

$$= \cdots$$

$$= T^k(P^*(\hat{q}_0, \tilde{\theta}_{new}), \tilde{\theta}_{new})$$

$$= T^k(P^*(\bar{q}_{old}, \tilde{\theta}_{new}), \tilde{\theta}_{new}). \quad (69)$$

Now we consider two cases.

(i) If $P^*(\tilde{q}, \bar{\theta})$ is invariant to $\tilde{\theta}$, we have $P^*(\bar{q}_{old}, \tilde{\theta}_{new}) = \hat{p}_{old}^*$. As a result, $\tilde{E}_m[\tilde{p}^*] = T^k(\hat{p}_{old}^*, \tilde{\theta}_{new})$. This is exactly the conjecture in condition (35) in the definition of Cobweb($k$) solution. The level-$k$ solution and the Cobweb($k$) solution impose the same price conjectures and give rise to the same observables.

(ii) If we modify the Cobweb solution concept so that the initial price conjecture is given by $\hat{p}_0 = P^*(\bar{q}_{old}, \tilde{\theta}_{new})$. Then the RHS of the conjecture in condition (35) in the definition of Cobweb($k$) solution becomes exactly equal to

$$T^k(P^*(\bar{q}_{old}, \tilde{\theta}_{new}), \tilde{\theta}_{new}) = P^*(\hat{q}_k, \tilde{\theta}_{new}).$$

As a result, the level-$k$ solution and the Cobweb($k$) solution impose the same price conjectures and give rise to the same observables.

**Proof of Corollary 4.** The result follows from Proposition 7 and case (i) in the proof of Proposition 8.
Proof of Proposition 9. From conditions (5) and (66), we have, for all $t \geq 0$,
\[
\begin{align*}
\frac{d}{dt} \left( \hat{p}^* (t) - \bar{p}_{old} \right) &= \left( \frac{\partial T}{\partial \hat{p}^*} - 1 \right) \left( \hat{p}^* (t) - \bar{p}_{old} \right) + \frac{\partial T}{\partial \theta} \left( \bar{\theta}_{new} - \bar{\theta}_{old} \right) \\
&= - (1 - \alpha) \left( \left( \hat{p}^* (t) - \bar{p}_{old}^* \right) - \left( \bar{p}_{new}^* - \bar{p}_{old}^* \right) \right).
\end{align*}
\]
Together with $\hat{p}^*(0) = \bar{p}_{old}^*$, we have
\[
\hat{p}^* (t) - \bar{p}_{old} = \left( \bar{p}_{new}^* - \bar{p}_{old}^* \right) \left( 1 - e^{-(1-\alpha)t} \right),
\]
As a result, we have, in the reflective equilibrium economy,
\[
\hat{p}^* = \bar{p}_{old} + w_{ref} (T) \left( \bar{p}_{new}^* - \bar{p}_{old}^* \right),
\]
in which $w_{ref} (T) = \left( 1 - e^{-(1-\alpha)t} \right)$. Together with Lemma 4 and condition (62), we have, for any $T \geq 0$, there exists a $T'$ such that the level-$T$ reflective equilibrium conjecture $\hat{p}^*$ coincides with the Tâtonnement($T'$) conjecture $\hat{p}^*$, and vice versa. Given part (i) of both Definition (5) and Definition (1), the level-$T$ reflective equilibrium also shares the same economic outcomes with the Tâtonnement($T'$) solution. The equivalence with the incomplete-information variant then follows from Corollary 3.

Proof of Proposition 10. We first prove condition (41). From condition (40) together with the fact that $\bar{p}_{old} = T(\bar{p}_{old}^*, \theta_{new}) = 0$, we have $\hat{p}^* - \bar{p}_{old} = \mu T(\hat{p}^* - \bar{p}_{old}, \Delta \bar{\theta})$. Iterating, we have
\[
\hat{p}^* - \bar{p}_{old} = \gamma (1 - \alpha) \sum_{h=1}^{\infty} \alpha^{h-1} \mu^h \Delta \bar{\theta} = \frac{\gamma (1 - \alpha) \mu}{1 - \alpha \mu} \Delta \bar{\theta} = \pi (\mu) \left( \hat{p}_{new}^* - \bar{p}_{old}^* \right),
\]
where $\gamma = \frac{\partial T}{\partial \theta} = \frac{\hat{p}^*}{1 - \alpha}$, as defined in condition (64), and where $\pi (\mu) = \frac{(1-\alpha)\mu}{1-\alpha \mu}$ is the same function as the one defined in Lemma 6. This proves condition (41).

Then, from conditions (31) and (41), we know, for any Gabaix-like variant with discount $\mu \in (0,1)$, there exists an incomplete-information economy with parameter $\lambda = \mu$ such that, for any realization of $\Delta \bar{\theta}$, the average rational expectation $E [\hat{p}^*]$ in the latter coincides with the irrational conjecture $\hat{p}^*$ in the former. Then, the two economies predict the same observable change in $\bar{q}$ from Lemma 3. The converse can be proved similarly.

Proof of Lemma 8. Fix a period $t$ and a marketplace $m$. Because of the linearity of preferences in consumption, we can express the optimal (log-linearized) choices of any household $i \in I (m, t)$ as follows:
\[
n_{i,t} = \frac{1}{\eta} w_{m,t} \quad \text{and} \quad k_{i,t} = \theta_m + \frac{1}{2} \bar{\Delta}_{m,t} \left[ p_{M(i,t+1),i,t+1} \right].
\]
The first part of this condition gives the optimal supply of labor; the second condition is the Euler condition and characterizes optimal capital accumulation. As households in the same marketplace share the same belief, we have, for all $i \in I (m, t)$, $n_{i,t} = \ell_{m,t}$ and
\[
k_{i,t} = k_{m,t} \equiv \int_{i \in I (m,t)} k_{i,t} di,
\]
Turning to the local firm, on the other hand, we have
\[ w_{m,t} = q_{m,t} - \ell_{m,t}, \quad p_{m,t} = q_{m,t} - \kappa_{m,t} \quad \text{and} \quad p_{m,i,t} - p_{m,t} = \frac{1}{\sigma} (\kappa_{m,t} - k_{i,t-1}), \]  

where \( p_{m,t} = \int_{t \in I(m,t)} p_{m,i,t} \, di \) is the (log-linearized) ideal price index for the capital composite in marketplace \( m \). The first part of the above condition gives the firm’s demand for labor; the second part gives its demand for the capital composite; the third part gives its demand for each particular capital variety.

By imposing market clearing in the labor market, and using the household’s supply of labor and the firm’s demand for labor, we get

\[ \ell_{m,t} = \frac{1}{1+\eta} q_{m,t} \quad \text{and} \quad w_{m,t} = \frac{\eta}{1+\eta} q_{m,t}. \]  

By the production function, on the other hand, we have \( q_{m,t} = \omega \kappa_{m,t} + (1-\omega) \ell_{m,t} \). It follows that

\[ q_{m,t} = \psi \kappa_{m,t}, \]  

where \( \psi = \frac{(1+\eta)\omega}{\eta+\omega} \in (0,1) \). By the firm’s demand for the capital composite, we then get

\[ p_{m,t} = -\chi \kappa_{m,t}, \]  

where \( \chi = \frac{\omega}{\eta + \omega} \in (0,1) \). Combining the above results, we infer that the local capital stock \( \kappa_{m,t} \) is a sufficient statistic for local quantities and local prices. By the same token, the aggregate investment in period \( t-1 \) (which is the capital stock in period \( t \)) is a sufficient statistic for aggregate outcomes in period \( t \).

Let \( \bar{q}_t \equiv \int q_{m,t} \, dm \) and \( \bar{\ell}_t \equiv \int \ell_{m,t} \, dm \) denote the aggregate levels of, respectively, output and employment; let \( \bar{w}_t \equiv \int w_{m,t} \, dm \) and \( \bar{p}_t \equiv \int p_{m,t} \, dm \) denote, respectively, the average wage and the average price of capital; and finally let \( \bar{k}_{t-1} \equiv \int k_{m,t-1} \, dm \equiv \int \kappa_{m,t} \, dm \) denote the aggregate investment in period \( t-1 \) (with the convention that \( \bar{k}_{-1} = 0 \)).

We know there exists a known linear vector function \( F \) such that, for every \( m \) and every \( t \),

\[ (q_{m,t}, \ell_{m,t}, w_{m,t}, p_{m,t}) = F(\kappa_{m,t}) \quad \text{and} \quad (\bar{q}_t, \bar{\ell}_t, \bar{w}_t, \bar{p}_t) = F(\bar{k}_{t-1}). \]

Note that this characterization has relied only on Assumptions 1–3. This mirrors the characterization of the “afternoon outcomes” in our baseline model. We next use the above results together with Assumption 4 to characterize the optimal investment choices. This mirrors the characterization of the “morning outcomes”.

Fix a period \( t \) and a marketplace \( m \), consider any household \( i \in I(m,t) \), and let \( m' = M(i,t+1) \) denote the location of that household in period \( t+1 \). Thanks to Assumption 4, the household can reason that, regardless of what \( m' \) turns out to be, the price for her own capital will satisfy

\[ p_{m',t+1} = p_{m',t+1} + \frac{1}{\sigma} (\kappa_{m',t+1} - k_{i,t}) = \left(1 - \frac{1}{\chi \sigma}\right) p_{m',t+1} - \frac{1}{\sigma} k_{i,t}, \]  

Next, because a household expects to stay in her current marketplace with probability \( \rho \) and to be randomly reallocated with the remaining probability, her expectation of \( p_{m',t+1} \) must satisfy

\[ \mathbb{E}_{m,t} [p_{m',t+1}] = \rho \mathbb{E}_{m,t} [p_{m,t+1}] + (1-\rho) \mathbb{E}_{m,t} [\bar{p}_{t+1}], \]  

Furthermore, because the household knows that \( p_{m,t+1} \) will satisfy \( p_{m,t+1} = -\chi \kappa_{m,t+1} \), and because the household also knows that \( \kappa_{m,t+1} \) will be given by mixture of the investment made by the current households in marketplace \( m \) and of the investment made in a random other marketplace (which will become \( m \)'s match in period \( t+1 \)), the following is true:
Finally, because the household can reason that all other households in her marketplace choose the same investment as herself, and because $p_{t+1} = -\chi \tilde{k}_t$, we can re-write that above as follows:

$$\hat{E}_{m,t}[p_{m,t+1}] = -\chi \hat{E}_{m,t} + (1 - \rho) \hat{E}_{m,t} [\tilde{p}_{t+1}].$$  \hspace{1cm} (79)

Combining (78) and (79), we infer that

$$\hat{E}_{m,t}[p_{m',t+1}] = -\rho^2 \chi k_{i,t} + (1 - \rho^2) \hat{E}_{m,t} [\tilde{p}_{t+1}].$$  \hspace{1cm} (80)

Plugging conditions (77) and (80) into condition (71), we have that, for every household $i$,

$$k_{i,t} = \theta_m + \frac{1}{\phi} \left( \left( 1 - \frac{1}{\chi \sigma} \right) \left( -\rho^2 \chi k_{i,t} + (1 - \rho^2) \hat{E}_{m,t}[\tilde{p}_{m+1}] \right) - \frac{1}{\chi} k_{i,t} \right),$$

where $m = M (i, t)$ and $m' = M (i, t + 1)$. Collecting terms and using the fact that $k_{i,t} = k_{m,t}$, we get\footnote{Note that, the denominator, $\sigma \phi + (\sigma \chi - 1) \rho^2 + 1 = \sigma \phi + \sigma \chi \rho^2 + 1 - \rho^2 > 0.$}

$$k_{m,t} = \frac{\sigma \phi}{\sigma \phi + \sigma \chi \rho^2 + 1 - \rho^2} \theta_m + \frac{1}{\sigma \phi + \sigma \chi \rho^2 + 1 - \rho^2} \hat{E}_{m,t}[\tilde{p}_{t+1}].$$  \hspace{1cm} (81)

This gives investment as a function of the local fundamental and the local subjective beliefs of the next-period average return to capital.

**Proof of Proposition 11.** We first prove conditions (43) and (44), whose derivation were omitted from the main text. Under the REE concept together with common knowledge of $\tilde{\theta}$ and of $\tilde{p}_{t+1}$, we have that, for all $i$ and all $t$,

$$\hat{E}_{m,t} [\tilde{p}_{t+1}] = E_t [\tilde{p}_{t+1}],$$

where $E_t$ denotes the rational expectation conditional on the information that is commonly available in period $t$. Using the above in Lemma 8 and aggregating, we get

$$\tilde{k}_t = K \left( E_t [\tilde{p}_{t+1}], \tilde{\theta} \right).$$

Because $\tilde{p}_{t+1} = -\chi \tilde{k}_t$, we can rewrite the above as

$$\tilde{p}_{t+1} = T \left( E_t [\tilde{p}_{t+1}], \tilde{\theta} \right),$$

where $T(\cdot) \equiv -\chi K(\cdot)$. Since both $\tilde{\theta}$ and $E_t [\tilde{p}_{t+1}]$ are commonly known in period $t$, so is $\tilde{p}_{t+1}$. We can thus restate the above as

$$\tilde{p}_{t+1} = T \left( \tilde{p}_{t+1}, \tilde{\theta} \right) \forall t \geq 0.$$

From condition (81), the slope of $T$ is then given by

$$\alpha \equiv \frac{\partial T}{\partial p} = \frac{(1 - \sigma \chi) (1 - \rho^2)}{\sigma \phi + \sigma \chi \rho^2 + (1 - \rho^2)},$$

where

$$\sigma \phi + (\sigma \chi - 1) \rho^2 + 1 = \sigma \phi + \sigma \chi \rho^2 + 1 - \rho^2 > 0.$$
where $\chi = \frac{\eta(1-\omega)}{\eta+\omega}$, as defined above. Note then that, since $\rho < 1$ and $\sigma \phi + \sigma \chi \rho^2 + (1 - \rho^2) > 0$ necessarily, we have that $\alpha > 0$ [resp., $\alpha < 0$] if and only if $\sigma \chi < 1$ [resp., $\alpha > 0$].

Now let

$$e^{\text{micro}} = \frac{\partial K}{\partial \theta} = \frac{\sigma \phi}{\sigma \phi + \sigma \chi \rho^2 + (1 - \rho^2)} > 0 \quad \text{and} \quad e^{\text{Macro}} = \frac{\partial K}{\partial \rho} + \frac{\partial K}{\partial \rho} \frac{\partial \rho}{\partial \theta}$$

Proposition 11 then follows from condition (45) directly. Furthermore, it is straightforward to check the GE effect is given by

$$GE = \frac{\partial K}{\partial \rho} \frac{\partial \rho}{\partial \theta} = \frac{\alpha}{1 - \alpha} e^{\text{micro}},$$

which means that the GE effect amplifies the PE effect (and $e^{\text{Macro}} > e^{\text{micro}}$) when $\alpha > 0$, whereas the opposite is true when $\alpha < 0$.$^{52}$

**Proof of Lemma 9.** As discussed in the main text, starting $t \geq 1$, it is as if agents each marketplace exchanges its information with another randomly matched marketplace. As a result, at period $t = 1$, agents in any marketplace $m$ will have two independent signals about the aggregate shock $\Delta \bar{\theta}$,

$$s_m = \Delta \bar{\theta} + v_m \quad \text{and} \quad s_{m'} = \Delta \bar{\theta} + v_{m'},$$

where $m'$ is the marketplace with which $m$ is matched at period $t$, $v_m$ and $v_{m'}$ is an idiosyncratic noise term, drawn i.i.d. from $N(0, \sigma^2)$. Similarly, at period $t = 2$, agents in any marketplace $m$ will have 4 signals about $\Delta \bar{\theta}$. Two of them are the signals they already receive at $t = 1$. The other two are new, from the new marketplace with which $m$ is matched at period $t = 2$. By induction, it is as if, at period $t \geq 0$, each marketplace $m$ have a total of $2^t$ signals of the form $s_j = \Delta \bar{\theta} + v_j$, where $v_j$ is an idiosyncratic noise term, drawn from $N(0, \sigma^2)$. As we have a continuum of markets but discrete time, the probability of a marketplace receives a “repetitive” signals through the matching place is always zero. We can henceforth view the $2^t$ signals as i.i.d. As a result, we have

$$\bar{E}_t[\Delta \bar{\theta}] = \lambda_t \Delta \bar{\theta} \quad \text{and} \quad \bar{E}_t[\bar{\theta}] = \bar{\theta}_{old} + \lambda_t \Delta \bar{\theta} \quad \forall t \geq 0,$$

where $\lambda_t = \frac{2^t \sigma^2}{2^t \sigma^2 + \sigma^2}$ and $\lambda_t \to 1$ as $t \to \infty$.

Iterating condition (82) by taking average expectations of both sides, we have

$$\bar{E}_t^h[\Delta \bar{\theta}] = \lambda_t^h \Delta \bar{\theta} \quad \text{and} \quad \bar{E}_t^h[\bar{\theta}] = \bar{\theta}_{old} + \lambda_t^h \Delta \bar{\theta} \quad \forall t \geq 0 \text{ and } h \geq 1.$$

This proves parts (i) and (iii) of Lemma 9. To prove part (ii), note that, from Lemma 8, local investment is given by

$$k_{m,t} = K \left(E_{m,t}[\bar{p}_{t+1}], \theta_m\right),$$

where $K$ is the same function as before and $E_{m,t}[\cdot]$ is the rational expectation conditional on the information that is available to marketplace $m$ in period $t$. Together with condition (76), we get the following fixed-point relation between the realized price $\bar{p}_{t+1}$ and the average expectation of it in period $t$

$$\bar{p}_{t+1} = T \left( \bar{E}_t[\bar{p}_{t+1}], \bar{\theta} \right),$$

where $T$ is the same mapping as defined in condition 43. Similarly to Corollary 2 in our baseline framework, we can thus express the equilibrium expectations of the price of capital at any given period $t$ as a linear combination of the

$^{52}$Note that, as stated in the main text, the underlying parameters are restricted so that $\alpha \in (-1, 1)$.
contemporaneous hierarchy of beliefs of the underlying fundamentals:

\[ E_t [\tilde{p}_{t+1}] = \gamma (1 - \alpha) \sum_{h=1}^{\infty} \alpha^{h-1} \tilde{E}_t^h [\tilde{\theta}] , \]  

where \( \gamma \equiv \frac{\partial \bar{p}}{\partial \bar{\theta}} \) is the elasticity of the price with respect to \( \tilde{\theta} \) in the frictionless benchmark and where \( \alpha \equiv \frac{\partial T}{\partial p} \) is the slope of the mapping \( T \). Combining this result with Lemma 9, we have

\[ E_t [\tilde{p}_{t+1}] = \gamma \bar{\theta}_{old} + \gamma \frac{(1 - \alpha) \lambda}{1 - \alpha \lambda} \Delta \bar{\theta} = \bar{p}_{old} + \pi (\lambda_t) (\bar{p}_{new} - \bar{p}_{old}) , \]

where \( \pi (\lambda) = \frac{(1 - \alpha) \lambda}{1 - \alpha \lambda} \) is the same as the one in Lemma 6. As noted there, \( \pi \) is continuous and strictly increasing in \( \lambda \), with \( \pi (0) = 0 \) and \( \pi (1) = 1 \).

**Proof of Proposition 12.** The result follows directly from aggregating condition (83) and Lemma 9.

**Proof of Proposition 13.** From the proof of Proposition 11, \( \epsilon^{Macro} = \frac{1}{1-\alpha} \epsilon^{micro} \). By normalizing \( \epsilon^{Macro} = 1 \), we have \( \epsilon^{micro} = PE = 1 - \alpha \) and, similarly, \( GE = \alpha \). From Proposition 12, we have

\[ \tilde{k}_t = \bar{k}_{old} + \{1 - \alpha + \pi (\lambda_t) \alpha\} \Delta \bar{\theta} = \bar{k}_{new} - \frac{\alpha (1 - \lambda_t)}{1 - \alpha \lambda_t} \Delta \bar{\theta} \]

Let \( g (\alpha, \lambda) \equiv \frac{\alpha (1 - \alpha)}{1 - \alpha \lambda} \), for all \( \alpha \in (-1, 1) \) and all \( \lambda \in (0, 1) \). Note that \( g (0, \lambda) = 0 \) and that \( |g (\alpha, \lambda)| \) increases in \( |\alpha| \) for all \( \lambda \in (0, 1) \). As a result, for any \( t \geq 0 \), \( \tilde{k}_t \) is further away from \( \bar{k}_{new} \) the larger \( |\alpha| \) is.

**Proof of Proposition 14.** We first prove condition (88). From condition (86), we have

\[ \hat{P}(t) - \bar{p}_{old} = (\bar{p}_{new} - \bar{p}_{old}) \left(1 - e^{\frac{w_t}{\bar{p}_{old}}}ight) . \]

Therefore, for all \( t \), we have that

\[ \hat{p}_{t+1} = \bar{p}_{old} + w_t (\bar{p}_{new} - \bar{p}_{old}) \]

with

\[ w_t = 1 - e^{\frac{N(t)}{\bar{p}_{old}}} f(t) . \]

Because \( \frac{\partial N}{\partial p} < 0 \) and \( f \) is positively valued and strictly increasing, we have that \( w_t \in (0, 1) \) for all \( t \) and that the sequence \( \{w_t\} \) is strictly increasing.

Now we turn to the proof of Proposition 14. By Lemma 8, the local and the aggregate level of investment is then given by, respectively,

\[ k_{m,t} = K (\hat{p}_{t+1}, \theta_m) \text{ and } \tilde{k}_t = K (\hat{p}_{t+1}, \tilde{\theta}) , \]

where \( K \) is the same function as before. Condition (89) the result follows directly from condition (85), Lemma 8 and the definition of \( \epsilon^{micro} \) and \( \epsilon^{Macro} \) in the proof of Lemma 11.

**Appendix C. Tâtonnement Dynamics**

In this appendix we define and characterize the Tâtonnement variant that is briefly discussed in Subsection 8.3. Let \( \bar{N} (\bar{p}, \bar{\theta}) = -\frac{1}{\lambda} \bar{p} - K (\bar{p}, \bar{\theta}) \) measure the excess aggregate demand for capital that obtains in any given period if both
the average price of capital and the previous-period expectation of it are given by \( p \).

Next, let the function \( \hat{P}(\cdot) \) be the solution to the following ODE:

\[
\frac{d\hat{P}(\tau)}{d\tau} = \mathcal{N}\left(\hat{P}(\tau), \tilde{\theta}_{\text{new}}\right) \quad \forall \tau \geq 0
\]

(86)

with initial condition \( \hat{P}(0) = \bar{p}_{\text{old}} \). Note that \( \hat{P}(\tau) \) is defined in the same fashion as in Definition 1 and identifies the price conjecture generated from the Tâtonnement-like cognitive process when its depth, or the number of rounds, is \( \tau \). Finally, specify the period-\( t \) conjecture in our dynamic economy as follows:

\[
\hat{E}_{m,t}[\hat{p}_{t+1}] = \hat{p}_{t+1} = \hat{P}(f(t))
\]

(87)

where \( f : \mathbb{N} \to \mathbb{R}^+ \) is a function that maps the calendar time to Tâtonnement rounds. This function is assumed to be strictly increasing—so that more rounds require more time or, conversely, time helps the agents become “deeper thinkers”—but is otherwise a “free parameter” that controls the speed of adjustment in the relevant conjectures.

This construction yields a simple translation of the analysis in Section 5 to the present framework. In particular, it is straightforward to check that there exists a strictly increasing sequence \( \{w_t\}_{t=0}^{\infty} \), with \( w_t \in (0, 1) \) for all \( t \), such that the period-\( t \) conjecture about the period-(\( t + 1 \)) price of capital satisfies

\[
\hat{p}_{t+1} = \bar{p}_{\text{old}} + w_t(\bar{p}_{\text{new}} - \bar{p}_{\text{old}}).
\]

(88)

This is similar to Lemma 4 in our baseline model, except that now the weight \( w \) increases with time. Combing the above with Lemma 8, we then obtain the following characterization of the dynamic response of aggregate investment.

**Proposition 14.** In the Tâtonnement variant described above, there exists a strictly increasing sequence \( \{w_t\}_{t=0}^{\infty} \), with \( w_t \in (0, 1) \) for all \( t \), such that

\[
\bar{k}_t = \bar{k}_{\text{old}} + \left\{\epsilon_{\text{micro}} + w_t(\epsilon_{\text{macro}} - \epsilon_{\text{micro}})\right\} \Delta \bar{\theta}, \quad \forall t.
\]

(89)

As explained in the main text, this means that the GE effect is inactive in the short run but builds force as time passes. The result is illustrated in Figure 4 in the main text, letting \( f(0) \approx 0 \) and \( f(\infty) \approx 1 \).

---

53To understand the formula for \( \mathcal{N} \), take any \( t \geq 1 \). From condition (76), the average demand for capital is given by \( \bar{k}_{t} = -\frac{1}{X} \hat{p}_t \). Next, suppose that all agents expect, in period \( t - 1 \), that the period-\( t \) average price of capital will be \( \hat{p}_t \).

Then, from Lemma 8, we have that the average investment in period \( t - 1 \), and therefore also the average supply of capital in period \( t \), is given by \( k_{t-1} = K(\hat{p}_t, \hat{\theta}) \). It follows that the excess demand for capital in period \( t \) equals \( -\frac{1}{X} \hat{p}_t - K(\hat{p}_t, \hat{\theta}) \), which explains the formula for \( \mathcal{N} \) used above. Future reference, let us also note that the excess demand is necessarily downward sloping: \( \frac{\partial \mathcal{N}}{\partial \hat{p}_t} = -\frac{1}{X} (1 - \alpha) < 0 \).
