BENGTHOLMSTRÖM

MANAGERIAL INCENTIVE PROBLEMS—
A DYNAMIC PERSPECTIVE

INTRODUCTION

It is well understood by now that informational externalities may place
special demands on the organization of economic exchange. Simple price-
mediated markets will frequently fail in the presence of asymmetric in-
formation. In that case, more elaborate contractual arrangements have to be
used as substitutes for the price system. Lately, considerable effort has
been devoted to the analysis of contracting under incomplete information
with the objective to understand the range of economic institutions that
emerge in response to the failure of the price system.

The analysis of moral hazard has played a prominent role in this de-
velopment.1) Moral hazard problems arise when, for one reason or another,
transacting parties cannot contract contingent on the delivery of the
good. For instance, in buying labor services it may be that the amount of
labor supplied is not directly observable, precluding a simple exchange of
wage for labor. As a partial remedy to this problem, an imperfect, mutu-
ally observed signal about the supply of labor can be used as a proxy in
the contract. Frequently, output is taken as such a proxy. The drawback is
that output is often influenced by other factors than labor input, which
induce undesirable risk into the contract. One is therefore faced with a
tradeoff between allocating risk associated with incomplete observability and providing incentives for a proper supply of labor. Gaining insight into this tradeoff is important not only for understanding contracting in the small (e.g. managerial incentive schemes), but also because it is closely related to the fundamental tension between equity and efficiency in the society as a whole.

While our understanding of moral hazard has advanced a lot in past years, it is clear that much work remains. An important question that has received little attention until very recently concerns the effect time has on incentives. Intuitively, time should have a beneficial impact on policing moral hazard, because it permits a longer series of observations and thereby more accurate inferences about unobservable behavior. This intuition has been made precise in work by Radner (1981) and Rubinstein (1981), who show that explicit long-term contracts can be written, which reduce incentive costs to zero when there is no discounting. Fama (1980) reaches this same conclusion using a conceptually different approach. He argues that market forces alone will frequently remove moral hazard problems, because managers will be concerned about their reputations in the labor market. Thus, there will be no need to resolve incentive problems using explicit contracts, since markets already provide efficient implicit incentive contracts.

The purpose of this paper is to investigate in some more detail Fama's rather provocative but interesting idea that career concerns induce efficient managerial behavior. Since Fama does not provide an explicit model of moral hazard, I start by formalizing his intuition. In the first part of the paper I present a model, based on that in Harris and Holmström (1981), which permits an explicit analysis of the manager's decision to supply labor. Under some narrow assumptions I show that Fama's conclusion is correct. In general, however, it is not. Risk-aversion and discounting place obvious limitations on the market's ability to police incentives adequately. More interesting therefore is my analysis of transient learning effects and non-linearities in technology, which both lead to inefficiencies even when there is no discounting and the manager is risk-neutral.

In the second part of the paper I consider the implications of reputation on managerial risk-taking. I argue that so far there has been no good explanation for why there should be an incentive problem with risk-taking in the first place, although this is clearly perceived to be an important issue in the real world. Using some simple examples I show then how a basic incompatibility in risk preferences between the manager and the firm arises from the manager's career concerns. Although I do not analyze how the problem should be resolved optimally, my analysis opens a new and promising direction for research on this question. Since managerial risk-taking problems appear specifically in a dynamic setting, this shows that, contrary to common intuition, time need not always be a blessing when it comes to incentive issues. It can create problems as well.

I. WORK INCENTIVES

I. The Basic Model

I will start by presenting the simplest model of reputation formation, leaving embellishments for later sections. Consider the following scenario of a manager operating in a competitive labor market. The manager is endowed with labor, which he sells in the market in exchange for consumption. No contingent contracts can be made, so we may envision that the manager is paid for his services in advance. In a one-period world he would have no incentive to work. The same is true in a multi-period world if there were no uncertainty about the characteristics of the agent. In order that there be some returns to the manager for good performance, it must be that present performance acts as information about future performance. Logically, this requires uncertainty about some characteristic of the manager. It is natural to take this characteristic to be talent, though many alternatives would do as well.

Let \( n \) be a quantified measure of the manager's talent and assume initially that it is fixed. The market has some prior beliefs about \( n \); specifically, assume that this prior is normally distributed with mean \( m_0 \) and precision (equal to the inverse of the variance) \( h_0 \). Over time, learning about \( n \) will occur through the observation of the manager's output. In period \( t \), this output is given by the technology:

\[
y_t = n + a_t + \varepsilon_t, \quad t = 1, 2, \ldots
\]

where \( a_t \in (0, \infty) \) is the manager's labor input and \( \varepsilon_t \) is a stochastic noise term. To be able to make inferences about \( n \) from (1) requires a dis-
distribution on \( \epsilon_t \); I take \( \epsilon_t \)'s to be independent and normally distributed with zero mean and precision \( h_c \).

The manager is assumed to be risk neutral with preferences given by an atemporal, separable utility function:

\[
U(c, a) = \sum_{t=1}^{\infty} \beta^{t-1} [g_t - g(a_t, \tau)]
\]

Disutility of labor is measured by \( g(.) \), which is increasing and convex. It is assumed that \( U(\cdot, \cdot) \) is publicly known.

In order to decide how much labor to supply, the manager has to calculate the impact of present output on future wages. On the other hand, the dependence of future wages on past output is a function of the manager's decision rule. Consequently, the decision rule and the wage functions are determined simultaneously in equilibrium. In general, this interaction may be quite complicated, but for the simple technology considered here, an explicit solution is easily obtained.

Let \( y_t = (y_1, \ldots, y_t) \) be the history of outputs up to time \( t \). This information is assumed known to the market and used as a basis for wage payments. Let \( w_t(y_t-1) \) be the wage in period \( t \) and \( a_t(y_t-1) \) be the manager's labor supply in the same period, both functions of the history. A competitive market, neutral to risk, will set:

\[
w_t(y_t-1) = E[y_t | y_t-1] = E[n_t | y_t-1] + a_t(y_t-1).
\]

This determines the wage in period \( t \) given that the manager's decision rule is known. On the other hand, given (3), the manager's decision rule solves:

\[
\max_{a_t(.)} \sum_{t=1}^{\infty} \beta^{t-1} [E w_t(y_t-1) - g(a_t(y_t-1))].
\]

The solution to (4) together with (3) determines equilibrium.

Notice that even though the market is not able to observe the manager's actions directly, it is able to infer them by solving (4). Therefore, observing \( y_t \) will in equilibrium be equivalent to observing the sequence:

\[
z_t = n + \epsilon_t = y_t - \alpha^*_t(y_t-1),
\]

where \( \alpha_t(y_t-1) \) represents the equilibrium decision rule. Through the observation of the sequence \( z_t \) the market learns about \( n \). In fact, this learning process is well-known given the normality and independence assumptions. The posterior distributions of \( n \) will stay normal with means and precisions given by:

\[
m_{t+1} = \frac{m_t + h_c n_t}{h_t + h_c} = \frac{h_t m_t + h_c n_t}{h_t + h_c},
\]

\[
h_{t+1} = h_t + h_c = h_t + h_c.
\]

Observe that the mean process \( (m_t) \) is a random walk with an incremental variance that declines deterministically to zero. In the limit \( n \) will become fully known.

Using (6), (3) can be written as:

\[
w_t(y_t-1) = m_t(z_t-1) + \alpha^*_t(y_t-1),
\]

where \( z_t = (z_1, \ldots, z_t) \). Taking expectations in (3) yields:

\[
E[w_t(y_t-1)] = \frac{h_t m_t}{h_t + h_c} + \frac{h_c}{h_t + h_c} \sum_{s=1}^{t} (m_s + \alpha_s - E\alpha^*_s(y_{s-1})).
\]

From (9) follows that the marginal return to \( a_1 \) in period \( t \) will be \( \alpha_t = \frac{h_c}{h_t} \) independently of the past (i.e., \( m_1 \)). Therefore, the solution to (4) is given by the first order conditions:

\[
y_t = \sum_{s=t}^{\infty} \beta^{s-1} \alpha_s = g'(a^*_t).
\]

Obviously, \( y_t \) is a declining sequence, and since the sum in (10) converges (because \( a_0 = 0 \), \( y_t \to 0 \). Consequently, the equilibrium sequence of labor inputs is declining and goes asymptotically towards zero as \( t \to \infty \).

The interpretation of this result is straightforward. As long as ability is unknown there are returns to supplying labor, because output will influence perceptions about ability. Indeed, labor is a substitute for abi-
lity. By increasing its supply, the manager can potentially bias the process of inference in his favor. Of course, in equilibrium this will not happen, because the market will know what effort level to expect and adjust the output measure accordingly (see 5)). In other words, the manager cannot fool the market. Yet, he is trapped in supplying the equilibrium level that is expected of him, because, as in a rat race, a lower supply of labor will bias the evaluation procedure against him.

Furthermore, the returns to labor supply are bigger the more there is uncertainty about ability, as can be seen from (10). Early in the process, when there is less information, the market puts more weight on the most recent output observation when revising its beliefs about \(n\). Eventually, \(n\) is revealed almost completely and new observations will have very little impact on beliefs. In the limit, therefore, there are no returns to trying to influence output and labor supply goes to zero.

I.2. The Stationary Case

The results above, of course, bear little relationship to efficient labor supply. Efficiency would require that \(a_t = \hat{a}\) for all \(t\), where \(\hat{a}\) is defined through:

\[
g'(a) = 1.
\]

The problem is that reputation formation is valuable only temporarily. To get a permanent reputation effect one must prevent \(n\) from becoming fully known. This is accomplished by assuming that ability is not fixed, but fluctuates over time. For instance, let ability progress according to the following process:

\[
\eta_{t+1} = \eta_t + \delta_t,
\]

where \(\delta_t\) are independent and normally distributed with mean zero and precision \(\sigma_\delta^2\).

The learning process will change in a slight, but important way. As before,

\[
m_{t+1} = \mu_t m_t + (1 - \mu_t) z_t,
\]

where

\[
u_t = \frac{d_t}{(\eta_t + c)}.
\]

However, \(\eta_{t+1}\) will be different. Let \(\hat{c}\) be the precision on \(n_{t+1}\) before observing \(y_{t+1}\). We have, as before:

\[
\hat{c}_t = h_t + \hat{c}_t
\]

From (12) follows (by independence):

\[
\frac{1}{\hat{c}_{t+1}} = \frac{1}{h_t} + \frac{1}{\hat{c}_t}.
\]

which with (15) gives:

\[
\eta_{t+1} = \frac{(h_t + \hat{c}_t) h_t}{(h_t + \hat{c}_t + \hat{c})}.
\]

Thus, \(\hat{c}\) will still progress deterministically, but will not go to infinity with \(t\) (as before), because the \(\sigma\)-shocks keep adding uncertainty. Instead, \(\hat{c}\) will approach a stationary state \(\hat{c}\) in which learning through output observations is just enough to offset the periodic increase in uncertainty from the \(\sigma\)-shocks.

It is somewhat easier to express the stationary state in terms of \(\mu_t\)'s, which, of course, are in a one-to-one correspondence with \(\eta_t\)'s through (14). Simple algebra gives the following recursion for the \(\mu_t\)'s:

\[
u_{t+1} = \frac{1}{2 + r - \mu_t},\]

where\n
\[
r = c_t / h_t = c_t / c_t^2.
\]

Stationarity requires \(\mu_{t+1} = \mu_t = \mu^*\). Solving for \(\mu^*\) from (17) yields:

\[
u^* = 1 + \frac{1}{2} r - \sqrt{\frac{1}{4} r^2 + r}.
\]

Notice that \(0 < \mu^* < 1\). If \(r = 0\), so that \(c\) has high variance relative to \(\sigma\), then \(\mu = 1\). In that case, the updating of \(m_t\) occurs slowly (see (13)). The reverse holds true if \(r = 1\).

In terms of \(\mu^*\), the stationary level of the precision, \(\eta^*\), is (using (14) and (19)).
(20) \[ h^* = \frac{h^*}{1 - \mu^*} \]

This settles the stationary learning process. Next, consider the ramifications on incentives. Following the earlier reasoning, the optimal labor supply, \( \alpha_t^* \), is given by:

(21) \[ \gamma_t \equiv (1 - \mu_t) \sum_{t=1}^{\infty} (1 - \gamma_t) (1 - \gamma_t) = g'(a_t^*) \]

In the stationary state \( \mu^* = \mu^* \). Substituting this into (21) implies that the stationary labor supply, \( \alpha^* \), satisfies:

(22) \[ \beta(1 - \mu^*) = g'(a^*) \]

Notice that the left-hand side is between 0 and 1, so \( \alpha^* < \alpha \), the efficient level of labor supply. From (22) we also reach Fama's major conclusion: if \( \beta = 1 \), then \( g'(a^*) = 1 \), which means that the stationary state is efficient. It is rather striking that this occurs as soon as we add any amount of noise in the \( \eta \)-process. With \( \beta = 1 \), efficient labor supply is independent of the degree of this noise though the noiseless case leads to no labor supply as was shown in the previous section. This discontinuity disappears as soon as \( \beta < 1 \). Then a small variance of \( \epsilon_t \) relative to \( \epsilon_t \) implies a \( \mu^* \) close to 1 and a stationary labor supply close to 0.

The general implications of (22) can be summarized by the following:

**Proposition 1:** The stationary level of labor supply \( \alpha^* \) is never greater than the efficient level of labor supply \( \alpha \). It is equal to \( \alpha \) if \( \beta = 1 \) and \( \sigma^2, \sigma^2 > 0 \). It is closer to \( \alpha \) the bigger is \( \beta \), the higher is \( \sigma^2 \) and the lower is \( \sigma^2 \).

In words, the comparative statistics results tell us that reputation will work more effectively if the ability process is more stochastic or if the observations on outputs are more accurate. Both features will speed up learning and move forward the returns from labor investments, reducing the negative effects of discounting.

### 1.3. Transient Effects

Proposition 1 tells us how incentives depend on the discount rate and the degree of noise in output and ability. Next I will consider incentives before a stationary state is reached. This involves exploring the convergence to the stationary state, which in itself is important if the results in the previous section are to be taken seriously.

Again, it is easiest to work with the \( \mu_t \)'s. The dynamics of \( \mu_t \) is given by (17). From (17) follows that \( \mu_{t+1} \) is an increasing function of \( \mu_t \) and from (19) follows that there is exactly one stationary state within the interval \((0,1)\). These facts are recorded in Figure 1.

![Figure 1](image)

From Figure 1 it is seen that if one starts with a value \( \mu_1 < \mu^* \), \( \mu_t \) will converge from below to \( \mu^* \) and if one starts with \( \mu_1 > \mu^* \), \( \mu_t \) will converge from above to \( \mu^* \). The system is therefore stable. From the definition of \( \gamma_t \) (eg. (14)) it follows that the stability can be cast in terms of \( h_t \) as well. If \( h_1 < h^* \), \( h_t + h^* \) and if \( h_1 > h^* \), \( h_t + h^* \).

The dynamics of \( \alpha_t \) will follow by studying (21). Let me show first that \( \gamma_1 \) is a decreasing function of \( \mu_1 \). The coefficient \( \gamma_1 \) is the sum of the terms \((1 - \mu_1), \beta(1 - \mu_1)\mu_2, \beta^2(1 - \mu_1)\mu_2\mu_3 \), etc. If each term is decreasing in \( \mu_1 \), the same is obviously true for \( \gamma_1 \). This step is proved by induc-
tion. Suppose $b_5(u_1) = 1 - u_1 + u_2 - u_3 + u_4 - u_5$ is decreasing in $u_1$ and consider $b_{5+1}(u_1)$. One can write:

$$b_{5+1}(u_1) = \frac{(1-u_1)}{1-u_1} \cdot b_5(u_2) = (1-u_2) = (1-u_1)b_5(u_2)$$

by using (17), (18) and the definition of $u_t$. By the inductive hypothesis, $b_5(.)$ is decreasing. Since $u_2$ is increasing in $u_1$ by (17), it follows that $b_{5+1}(u_2)$ is decreasing in $u_1$. Consequently, $\gamma_1$ is decreasing as a function of $u_1$.

It follows, by the definitions of $\gamma_t$ and $u_t$, that $\{\gamma_t\}$ is a decreasing (increasing) sequence if $(u_t)$ is an increasing (decreasing) sequence. Recalling then that $u_t^*(+) = \gamma_t$ if $h_t < h^*$, I have established the following stability result.

Proposition 2: The sequence of optimal labor supply $(a_t^*)$ will converge monotonically to the stationary state $a^*$. If the initial precision of information about ability, $h_1$, is less than the stationary precision level $h^*$, the convergence of $a_t^*$ is from above. Conversely, $h_1 > h^*$ implies $a_t^* = a^*$.

![Figure 2](image)

The convergence result is illustrated in Figure 2. With the interpretation of $h$ as ability, it seems clear that $h_1 < h^*$ is the common case. Normally, we expect that the precision of information about ability increases as time goes on. The picture shows that in that case young people will over-

invest in labor supply because the returns from building a reputation are highest when the market information is most diffuse.

This seems to accord nicely with casual empiricism (including introspection). There is some scientific evidence as well. Meadoff and Abraham (1980) conducted a study where they measured the productivity of different age groups in various job categories. Though the evidence was not overwhelmingly strong, the study pointed towards the fact that young people are more productive. If one believes that equally able people are, roughly at least, placed in the same jobs, their findings imply that young people supply more labor.

To the extent that convergence to a stationary state is slow, which again will be the case if output is noisy relative to shocks in ability, the analysis above shows that there may be a substantial transient inefficiency even when there is no discounting.

I. 4. Scale Economies

Next I turn to changes in technology. The normality assumptions are not important as one can infer from Muth (1960). However, it is clear that the linearity in (1) and (12) is essential for efficiency. To show this in general seems both messy and uninteresting so I will only discuss the matter via some illuminating examples. To reduce complexity, assume that there is no noise in the observation of output. i.e., let $e_t \equiv 0$. Nothing pathological is introduced in this way. It merely implies that all returns from labor supply accrue in the next period since $u^* = 0$. Notice that with the earlier used linear technology, efficiency prevails in all periods in this special case.

Now, suppose output is given by

$$y_t = f(n_t) + e_t.$$  

(23)

I leave $e_t$ outside $f(.)$, because then efficiency simply requires that $a_t = a$ in all periods. Instead of interpreting $f(.)$ as a production function, one can view (23) as a way of making the learning process non-linear (and output non-symmetrically distributed). Because of this, there is no a priori reason to assume $f(.)$ is concave.
Let \( \eta_0 \) be the ability level inferred from the last observation. The manager's wage today is \( w_1 = Ef(\eta_1) + \tilde{a} \) under the assumption that \( a_1 = \tilde{a} \). The question is, will he choose \( a_1 = \tilde{a} \)? To answer this, the returns from \( a_1 \) have to be calculated. They will come from \( w_2 \) only, since \( u^* = 0 \). For \( w_2 \) we have the expression:

\[
(24) \quad w_2 = Ef(\eta_2) + a_2 = Ef(\tilde{\eta}_1 + \delta_1) + a_2 = \\
Ef(f^{-1}(\eta_0 + \delta_0 + a_1 - \tilde{a}) + \delta_1) + a_2.
\]

Here \( \tilde{\eta}_1 \) is the ability level that the market infers from \( y_1 \), by computing \( f^{-1}(y_1 - \tilde{a}) \). If \( a_1 \neq \tilde{a} \), then \( y_1 = f(\eta_0 + \delta_0) + a_1 - \tilde{a} \), and \( \tilde{\eta}_1 \neq \eta_1 \). The expectation in (24) is taken over \( \delta_0 \) and \( \delta_1 \) under the assumption that the manager knows no more about his ability than the market when choosing \( a_1 \). The marginal benefit from \( a_1 \) at \( a_1 = \tilde{a} \) is then:

\[
(25) \quad E \left[ f'(\eta_0 + \delta_0 + \delta_1) (f^{-1})'(f(\eta_0 + \delta_0)) \right] = \\
E \left[ f'(\eta_0 + \delta_0 + \delta_1)/f'(\eta_0 + \delta_0) \right].
\]

Obviously, this expression will generally differ from 1 as efficiency would require. For instance, if \( f'(\cdot) \) is convex (i.e., \( f''(\cdot) > 0 \)), then it is strictly greater than 1 (by Jensen's inequality). Thus (strong) convexity points to oversupply of labor. The reverse holds for (strong) concavity.

Another, perhaps more natural, example of non-linearity is the following:

\[
(26) \quad y_t = a_t n_t.
\]

If \( g(a_t) = 1/2 a_t^2 \), then efficiency requires \( a_t = \eta_t \). With this decision rule the marginal returns to today's effort can be easily calculated to be \( \eta_t^2 + a_t^2 \). The marginal return from output is, however, \( n_t \) according to (26). Thus, there will be overinvestment in labor when ability is perceived to be high and underinvestment when ability is perceived to be low. Labor input will vary more than efficiency would dictate.

A third class of cases with inefficient outcomes arises when job matching is introduced. Suppose managers are matched to jobs according to perceived ability. If output is linear in ability in each task, then optimal matching of persons to tasks will yield overall returns to ability which are convex (see Rosen [1981] for more on this point). This convexity will result in proportionately larger returns to labor from reputation than are the actual returns from production. Since this case is formally very similar to the previous example I omit a more detailed argument. The idea can perhaps be most easily grasped if we think of the returns from labor in a pure signalling model of schooling. In that case there is no productive value from students working hard for better grades. Yet, students do work hard, because of reputation effects, even though it is entirely wasteful from a social point of view.

The general point illustrated by the examples above, is, of course, that the returns from signalling need not be closely aligned with the returns to present output, unless the technology is linear.

1.5 Discussion

Fama has argued that in a dynamic perspective reputation effects will frequently be sufficient to police moral hazard problems without recourse to explicit output based contracts. The exercises above were conducted to explore the generality of such a statement. Although anything but general themselves, they suggest, to me at least, that quite restrictive conditions have to be imposed to reach efficiency.

The mere observation that a number of factors reduce the efficiency of market incentives is of limited interest. After all, there is plenty of empirical evidence that explicit incentive schemes as well as implicit wage structures are important in the real world. Furthermore, the most obvious reason for a need to contract has so far gone unmentioned: risk-aversion. The market incentives discussed above do not protect the manager at all against risk and as such they are clearly suboptimal.

Thus, there is little reason to doubt that contracts will play an important part in a fuller analysis of dynamic moral hazard. The value of the present analysis rests with the faith that even when contracts are included, some of the qualitative conclusions reached here will remain true; in particular, that the need for incentives which increase labor supply, is
small in the early stages of a manager’s career and in situations where returns to ability are convex.

II. Incentives for Risk Taking

Providing work incentives is only part of the managerial incentive problem. To secure proper behavior in the choice of investments is equally important. Firms frequently express a concern over the way their management takes risks. Some think their managers take too much risk; but perhaps more commonly managers, particularly the younger ones, are seen as overly risk averse.

Wilson (1968) and Ross (1973) have addressed the problem of designing reward schemes which induce correct incentives for risk taking. I would argue, however, that their models do not capture the essential aspect of the problem. The reason is that in their models an incentive problem arises only as a consequence of attempts to utilize the manager’s risk absorption capacity. This may be relevant in small, closely held firms. But in a firm of even modest size or in a publicly held corporation, gains from having the manager carry some risk are certainly negligible. The apparent solution (in their models at least) is to offer the manager a constant wage and ask him to act in the firm’s best interest. This will yield an outcome that for all practical purposes is efficient.3)

Thus in the Wilson-Ross model, there really is no incentive problem in the first place. So what can account for the common concern?

I think a major reason for incongruity in risk preferences stems from the manager’s career concerns.4 A large part of managerial talent relates to projecting investment returns and choosing the good prospects. If talent is not fully known, investment decisions become tasks that provide information about talent. Perceptions about talent, in turn, determine the manager’s future opportunity wage and this is what makes investments risky from the manager’s perspective even if income is not explicitly tied to profits. The solution suggested for the Wilson-Ross model (a constant income) is infeasible, because a manager who’s ability is perceived high will be bid away (see Harris and Holmström (1981)). I will elaborate on this idea in two examples below.

II.1 An Incongruity in Risk Preferences

Consider a manager who is in charge of choosing investment projects for a risk-neutral firm. He may be either talented or not. Talent is associated with the likelihood that investments are successful. Presently, the probability that he is talented is assessed to be by the firm as well as the manager.

Investments can either fail or succeed. Let $y_-$ be the payoff if a project fails and $y_+$ if it succeeds. The likelihood that a project succeeds is $\beta$ if the manager is talented and $\beta_N$ if he is not. Obviously, $\beta > \beta_N$. The overall probability of success is then:

\[
\Pi = \beta \pi + \beta_N (1-\pi).
\]

In this set-up, investment projects are characterized by the vector $I = (y_+, y_-, \beta, \beta_N)$ (or equivalently by the vector $(y_+, y_-, \beta, \beta_N)$). The pool of potential projects is a collection of such I’s. The manager’s expertise lies in observing this pool while others do not.

From the pool the manager will choose at most one project and propose it for investment.5) Such a proposal involves presenting the information I in a verifiable way to his superiors who will make the final decision. Thus, potential incentive problems are not associated with misrepresenting information about a proposed project, but with the possibility that the proposed project is not the best available alternative from the firm’s perspective.

I now show that hiding information will indeed be a problem. Let $\eta_+ (\eta_-)$ be the probability that the manager is talented given that the investment succeeds (fails). By Bayes’ rule:

\[
\eta_+ = \beta \eta / y_+, \quad \eta_- = (1-\beta) \eta / (1-\pi).
\]

The manager’s opportunity wage will be a function of the updated assessments above. What the exact relationship is depends on the exact specifi-
cation of the investment pool. Shortly, I will examine a case where opportunity wage is linear in \( n \), so let me proceed with this assumption. Without loss of generality, (27) then coincides with the payoffs for the manager. The expected value of the manager's risk is therefore:

\[
p_t \pi n/p + (1-p)(1-\pi) n/(1-p) = n.
\]

The fact that the expected value coincides with the prior probability of talent is actually more general. Since the manager's lotteries forms a martingale with respect to beliefs, it will be true whenever payoffs are linear functions of the posteriors.

If the manager is risk-neutral he is indifferent between all projects. He can therefore be expected to propose the project which the firm prefers most. For a risk-averse manager things are different. The expected return from undertaking an investment is no higher than abstaining from investments altogether. Since investing carries risk it is then clear that the manager would not like to invest at all. He will have an incentive to claim that no worthwhile investment opportunity was present in the pool of potential investments. Under the informational assumptions made, such a claim cannot be invalidated.

The analysis above shows that career concerns induce a genuine incongruity in risk preferences between the firm and the manager. To emphasize this point, notice that the risk facing the manager is quite different from the risk that is of concern to the firm. A key variable for the manager is the likelihood of success \( \pi \). The manager dislikes investments, which will reveal accurately whether he is a talented manager or not, since these investments make his income most risky. He prefers investments which leave him protected by exogenous reasons for investment failure. The firm, however, has no interest in \( \pi \), given p. 6. Instead, it is mainly concerned with the actual payoffs \( (y_-, y_+) \) of the project and these again are irrelevant for the manager.

Evidently, the manager has to be given some stake in the real outcome if preferences are to be brought closer together. Giving him a share of the firm may not be the best strategy, however, since it carries both downside and upside risk. A stock option could be a more valuable incentive, since it removes the downside risk. This would be an interesting conclusion in view of the prominent role options have played in managerial incentive plans, but verification of its validity has to await a more careful analysis.

II. 2. A "Lemons" Problem

My final example, an elaboration on the previous one, illustrates that if the manager cannot communicate investment risks in a verifiable way incentive problems get even more severe.

Let the investment pool consist of only one project. The project characteristics are \( I = (-1, +1, s, 1/2) \). The manager's only private information is the likelihood \( \pi \) that the project succeeds if he is talented. One can view \( s \) as a signal about the likelihood of success, which is relevant only if the manager has talent. From the firm's point of view, the manager should invest if \( s > 1/2 \), since the expected value, conditional on \( s \), is \( (2s - 1) \).

The firm does not know what \( s \) is, but assesses a uniform distribution to it. \( \mathbb{E}_X \text{ante} \), the value of the manager (i.e., his information) is then easily seen to be \( 1/4 \pi \). If the manager only lives for two periods, then no incentive problems arise in the second period and his opportunity wage will be \( 1/4 \pi \), where \( \pi \) is the revised talent assessment.

The posterior beliefs about talent will depend on the manager's decision rule. Suppose beliefs are updated under the assumption that the manager invests if \( z = 2s - 1 > 0 \). (i.e., if \( s > 1/2 \)). The posteriors on his talent will then be:

\[
\begin{align*}
n_+ &= 3n/(2n), \\
n_- &= n/(2-n).
\end{align*}
\]

Of course, if no investment is made the posterior is \( n_0 = \pi \). Will a risk neutral manager actually use \( z = 0 \) as his investment criterion? Simple algebra shows that he will invest if

\[
\frac{(1/2 + nz)}{2n} + \frac{3(1/2 - nz)}{2n} > 1.
\]
The left-hand side is increasing in \( z \) and the value at \( z = 0 \) is less than \( 1 \) (for \( n \neq 0, 1 \)). Consequently, the manager will use as his cutoff rate some \( \tilde{z} > 0 \). Thus, if a risk neutral manager is rewarded according to expected marginal product, computed based on the rule to invest if \( z \geq 0 \), he will not conform to this rule. He will take less risk, because of a concern for the negative talent evaluation that follows upon failure. More specifically, he realizes that the firm will update beliefs about talent conditional on the general knowledge that \( (z > 0) \) obtained (since an investment was made), which puts him in an unfavorable position if \( z \) is actually close to 0.

It is natural to ask whether there is another cutoff value \( \tilde{z} \) such that the manager wants to invest exactly when \( z \geq \tilde{z} \) given that he is paid his expected product in the second period and given that this expected product is calculated based on the updating rules that apply when \( z \geq \tilde{z} \) is the investment rule of the manager?

The updating rules for talent, conditional on investment when \( z \geq \tilde{z} \), are:

\[
\begin{align*}
\eta_+ &= n(3 + \tilde{z})/(2 + n + n\tilde{z}), \\
\eta_- &= n(1 - \tilde{z})/(2 - n - n\tilde{z}).
\end{align*}
\]

On the other hand the manager invests whenever \( z \) is such that:

\[
\eta_+ (1/2 - n\tilde{z}) + \eta_- (1/2 + n\tilde{z}) > n.
\]

Combining (32) and (33) gives the equilibrium condition for \( \tilde{z} \):

\[
\frac{(3 + \tilde{z})(1 - n\tilde{z})}{2 + n + n\tilde{z}} + \frac{(1 - \tilde{z})(1 - n\tilde{z})}{2 - n - n\tilde{z}} = 2.
\]

Equation (34) can be shown to have no other solution in \((-1, 1)\) than \( \tilde{z} = 1 \). As in Akerlof's (1970) "lemons" model, the only equilibrium is the degenerate one where no investments are made. Thus, if the manager cannot have his investment information validated it makes him more conservative. Even a risk neutral manager acts as if he is risk averse in this example.

II. 3. Discussion.

There are a number of reasons why the incentive problems described above may not be as severe as stated. For the same reasons as in Section I.4, it could be that payoffs are convex in talent, reducing the aversion to risk-taking. The manager may also know more about his talent than the firm. An undervalued manager would then be willing to take risk in order to prove himself implying that risk-taking in itself would be a signal of talent. The same would be true if talented managers would receive higher signals on average than less talented managers.

Indeed, possibilities like these suggest a rich agenda for future research and indicates that modelling risk-taking from a dynamic perspective is a fruitful approach. I note in passing that such models may also help us understand the puzzle why investment procedures in firms are so detailed and centralized. As the latter example showed, it may have as much to do with securing a proper evaluation of managerial talent as it has to do with controlling what projects get selected.

III. Concluding Remarks

This paper has explored some ramifications of the thesis that managerial incentive problems are closely tied to learning about managerial ability. It implies a dynamic perspective on incentive issues. The paper has raised rather than answered questions, but then awareness of issues is a first and important step towards resolving problems.

Regarding work incentives I conclude that one can certainly not make any sweeping arguments about moral hazard problems disappearing in the long-run. Contracts will clearly play an important role still. The relevant question to address then is whether the insights we have gained from studying one-period models will be significantly changed when looking at multi-period models. This of course, will require an explicit dynamic of contracting.
Regarding investment incentives, I note that dynamics is what seems to raise the problem in the first place, so in this case time appears to hurt rather than help reduce incentive costs. Perhaps this is the most interesting aspect of dynamics in the context of managerial incentives.

FOOTNOTES
1) For some recent work on moral hazard the reader is referred to Mirrless (1976), Harris and Raviv (1979), Holmström (1979) and Shavell (1979).
2) Since the manager is risk neutral and no contracts are considered, borrowing and saving can be ignored.
3) A similar point is made in Ross (1977).
4) An alternative reason is that work incentives will require that the manager is paid as a function of firm output and this in turn induces a difference in preferences for risk. The model by Grossman and Hart (1981) can formally account for this possibility, but they do not explore the consequences of such incongruity.
5) Assuming that at most one project is selected is without loss of generality if \( y_\cdot \) and \( y_\cdot \) are the same for all projects (and in a more general model with arbitrary investment outcomes).
6) This may not be generally true if the firm finds value in learning the manager's ability for purposes of placement.

Finländska producentvaruföretag och deras marknadskommunikation vid export och internationalisering

Internationellt sett har den ekonomiska utvecklingen under de senaste årtiondena lett till ökad växelverkan och ett större ekonomiskt beroende mellan olika länder. Utvecklingstrenden har varit den att industriprodukternas andel av världshandeln har ökat och utgör nu cirka 60%, medan en motsvarande minskning har skett i handeln med livsmedel och övriga lantbruksprodukter, skogsbruksprodukter samt malar och metaller.

Trots att Finlands export har diversifierats efter andra världskriget är den geografiskt fortfarande tämligen koncentrerad, vilket tydligt framgår av exempelvis följande siffror: av vår totala export 1981 gick 25% till Sovjetunionen, 35% till EG-länderna, huvudsakligen Storbritannien (10,6%), Österbundsrpubliken Tyskland (9,1%), Frankrike (3,9%), Nederländerna (3,4%) och Danmark (3,3%), och 20% till EFTA-länderna, främst Sverige (13,4%) och Norge (4,7%).

Den tillväxt och diversifiering som kännetecknade den finländska industriproduktionen under 1980-talet och början av 1970-talet möjliggjordes dels av en världsomfattande hög tillväxttakt med därav förändrad stark efterfrågeökning, dels av handelsutbytet med Sovjetunionen som erbjudit speciellt den finländska metallindustrin möjlighet att utveckla sina produkter och exporterar dem till den sovjetiska marknaden. Liknande möjligheter till fortsatt ökad efterfrågan på våra industriprodukter synes
