AND CINDY PALADINES**

ABSTRACT. Do celebrity endorsements matter for public health, and if so, how can celebrities communicate effectively? We conduct a nationwide Twitter experiment in Indonesia promoting vaccination. Celebrity messages are 72 percent more likely to be passed or liked than similar messages without celebrity imprimatur. Decomposing this, 79 percent of the celebrity effect comes from authorship, compared to passing on messages. Citing external medical sources decreases retweets by 27 percent. Phone surveys show that those randomly exposed to messaging have fewer incorrect beliefs and report more vaccination among friends and neighbors. The results can inform vaccination campaigns, such as for the COVID-19.

Date: May 13, 2021.

We thank Ran Abramitsky, Marcella Alsan, Nancy Baym, Emily Breza, Leo Bursztyn, Rebecca Diamond, Dean Eckles, Paul Goldsmith-Pinkham, Ben Golub, Mary Gray, Rema Hanna, Johannes Haushofer, Matt Jackson, Tyler McCormick, Madeline McKelway, Matthew Wai-Poi, Alex Wolitsky, and participants at various seminars for helpful discussions. Aaron Kaye, Nurzanty Khadijah, Devika Lakhote, Eva Lyubich, Sinead Maguire, Lina Marliani, Sebastian Steffen, Vincent Tanutama provided excellent research assistance. We thank Nila Moeloek, then Indonesian Special Envoy for Sustainable Development Goals, Diah Saminarsih, and their team for providing support for this project. This study was approved by IRBs at MIT (Protocol #1406006433) and Stanford (Protocol #31451), and registered in the AEA Social Science Registry (AEARCTR-0000757). Funding for this project came from the Australian Government Department of Foreign Affairs and Trade. The views expressed here are those of the authors only and do not represent those of any of the institutions or individuals acknowledged here.

1. INTRODUCTION

Social media has allowed celebrities to take an increasing role in social discourse. With millions of followers, celebrities have a channel to spread messages on many issues, including some far removed from their original reason for fame. Their participation in ongoing discussions can make issues prominent and shape the zeitgeist.

Examples abound. #BlackLivesMatter is perhaps the most-used social issue Twitter hashtag ever, with over 47 million uses in just the three weeks following the murder of George Floyd, and tens of millions more uses before and after. In public health, the #IceBucketChallenge, promoting awareness of Lou Gehrig’s disease, became the sixth most-used social issue hashtag ever following participation by celebrities, from Oprah to Bill Gates. Each of these campaigns was initiated by a less-well-known activist, but made prominent in part through celebrity participation. More recently, celebrities have been recruited by policymakers to participate in information campaigns in response to COVID-19 – including promoting social distancing, mask-wearing, and, most-recently, vaccine take-up.

Using celebrities effectively for a public health campaign, however, depends on what features of the celebrity messaging spur diffusion. Beyond the direct *reach* that celebrities have – they have numerous followers – there are several dimensions that one must consider for policy design. First, how much does celebrity *endorsement*, meaning involvement with the messaging beyond the simple fact that they have numerous followers, matter? Second, how much of an endorsement premium comes from a direct *authorship* effect, as opposed to relaying the message of others? Third, how much does inclusion of *credible sourcing* matter, particularly when celebrities are speaking on a topic removed from their core area of expertise, such as public health. Each of these has implications for whether and how to effectively deploy celebrity endorsements to encourage take-up of public health products, such as vaccines.

Yet whether celebrity endorsement is likely to matter in the context of public health remains a matter of public debate, especially since public health issues are often far from their main area of expertise. For instance, in a May 2021 New York Times article (Ives, 2021), epidemiologists and psychologists, based on focus groups, argue that celebrity endorsements may not address COVID-19 vaccine indifference and hesitancy.¹ Despite widespread interest in using celebrities to promote vaccination, there remains little rigorous empirical evidence on whether this matters, and if so, how to effectively design celebrity outreach campaigns.

Measuring and decomposing the endorsement, authorship, and credible sourcing effects, as well as measuring whether any of these campaigns have offline effects, is challenging. First, celebrities’ decisions about whether, and what, to say publicly are choice variables and influenced by the general information environment into which they are speaking. People

¹See <https://www.nytimes.com/2021/05/01/health/vaccinated-celebrities.html>

also consume information from so many sources that in most contexts it is also nearly impossible to isolate the response to a particular piece of information or exposure to a particular celebrity, either online or offline. And, in general, a given action by a celebrity bundles reach and endorsement, making it hard to disentangle precisely which messages have an impact and therefore how to design policy response.

To study these issues, we conducted an experiment through a nationwide immunization campaign on Twitter from 2015-2016 in Indonesia, in collaboration with the Indonesian Government’s Special Ambassador to the United Nations for Millennium Development Goals. Working with the Special Ambassador, we recruited 46 high-profile celebrities and organizations, with a total of over 11 million followers, each of whom gave us access to send up to 33 tweets or retweets promoting immunization from their accounts. The content and timing of these tweets was randomly chosen from a bank approved by the Indonesian Ministry of Health, all of which featured a campaign hashtag #AyoImunisasi (“Let’s Immunize”).

The experiment randomly varied the tweets along three key dimensions: (1) Did the celebrity / organization send the tweet directly, or did they retweet a message (drawn randomly from the same tweet library) sent by us from an ordinary (non-celebrity) user’s account?; (2) Did the tweet explicitly cite a public health source?; (3) When did the celebrity tweet? This variation allows us to decompose and measure the relative importance of endorsement, authorship, and credible sourcing effects. Moreover, by varying which celebrities tweet when, we can go further to ask whether an online public health campaign has meaningful offline effects overall. To the best of our knowledge, this is the only field experiment studying celebrity endorsements of vaccines, or of public health more broadly.

We study the effects of this induced variation in two ways. First, we use online reactions, i.e., likes and retweets, so we can observe the online reactions of every follower to each tweet.² Second, we also study the offline effects of exposure to the campaign by conducting phone surveys of Twitter users. By randomly allocating celebrity activity into one of several phases – either before or after the survey – we can examine whether individuals who follow celebrities randomized to tweet before the survey are more likely to have heard of the campaign, updated their beliefs, discussed immunization status with their friends and neighbors, and observed changes in immunization behavior among their friends, relatives, and neighbors.

We chose this setting for several reasons. Twitter is one of the most important mediums of information exchange in the world, with over 1 billion users. Indonesia is quite active on social media; for example, in 2012 its capital, Jakarta, originated the most tweets of any city worldwide. Twitter also has many useful features for our study. Because both the network (i.e., who sees whose tweets) and virtually all information flows over the network

²Note that on Twitter, a “like” is not pushed to one’s followers, while a “retweet” subsequently passes on the tweet to all of one’s followers. While sometimes individuals retweet tweets they disagree with, adding commentary or simply ironically, “liking” directly conveys approval.

(i.e., tweets and retweets) are public, we can precisely map who sees what information, as well as where they saw it, allowing us to observe how much exposure each user had to precise bits of information. By conducting an experiment, randomly varying who tweets what when, we can solve the identification problem of endogenous speaking behavior, as well as disentangle reach vs. endorsement effects. Immunization was chosen as it was a clear public health message, for which celebrities could rely on the Ministry of Health to provide trusted information, but for which there is still not universal uptake. And, because of the public nature of Twitter, we can observe people’s responses to information both online (by observing their online “liking” and “retweeting” behavior) and offline (by conducting a phone survey of Twitter users and linking their survey responses to whether they were randomly exposed on Twitter to information prior to the survey).

We begin by using our design, in combination with the structure of how information is passed on Twitter, to distinguish reach from endorsement - i.e., how much additional effect does the celebrity endorsement *per se* have, above and beyond the fact that the celebrity’s messages are directly seen by many followers. Messages in Twitter are passed on by retweeting a message to one’s followers. Crucially for our design, when a message is retweeted, the follower observes who originally composed the tweet, and who retweeted it directly to the follower, but not any intermediate steps in the path.

To see how this allows us to distinguish reach from endorsement, consider the difference between what happens when 1) we have a celebrity directly compose and tweet a message, compared to 2) when we have a celebrity retweet a message drawn from the same pool of tweets but originated by a normal citizen (whom we henceforth denote as “ordinary Joes and Janes”; these Joes/Janes are also participants in our campaigns).

Consider what happens when some celebrity followers (whom we denote F_1) retweet it to their followers, whom we denote F_2 , depicted in Figure 1. In the first case, Panel A, the followers-of-followers (F_2 s) observe that the celebrity authored the message and that F_1 retweeted it, as seen in Panel B. But in the second case, Panel C, when the celebrity retweeted a Joe/Jane message rather than composed it herself, the followers-of-followers of the celebrity (F_2 s) observe only that the Joe/Jane tweeted and that F_1 then retweeted for F_2 to see, as displayed in Panel D.

So F_2 is randomly blinded to the celebrity’s involvement in the latter case, as compared to the former: differences in F_2 ’s behavior correspond to differences due to knowing that the celebrity was involved.³ In the period we study, the ordering of the Twitter feed was strictly chronological, so this design manipulates whether the F_2 s know about the celebrities’ involvement without affecting how prominently the message appeared in their feed.

³A challenge is that the F_1 decision to retweet may be endogenous. We discuss this in detail in Section 3.1.1, and show that the results are largely similar in the subset of cases where F_1 s were also study participants whom we randomly selected and had retweet exogenously, and hence the sample of exposed F_2 s is identical.

We find a substantial endorsement effect. When an individual observes a message through a retweet, and that message was randomized to be originally composed by a celebrity rather than an ordinary individual, there is a 72 percent increase in the number of likes and retweets, compared to similar messages when the celebrity’s involvement was masked. We find similar results even when we restrict attention to those cases where F_1 s are participants in the experiment and we exogenously had them retweet the message, ensuring that whether the F_2 was exposed to the message in the first place was completely exogenous. This implies that the endorsement effect corresponds to 63-72 percent of the reason as to why a downstream follower (F_2) retweets a celebrity.

The preceding analysis does not distinguish between whether endorsement of a public health message matters because a downstream individual knows that a celebrity was involved per se, or because the celebrity actually authored the message. We therefore next further decompose the endorsement effect to understand the impact of celebrities speaking in their own voice (an ‘authorship’ effect) from the celebrity passing on the message of others. We use the same experimental variation, but look at behavior of the direct followers of celebrities (F_1 s), who see both the celebrities’ directly authored tweets and the celebrities’ retweets. Tweets directly-authored by celebrities are 280 percent more likely to be retweeted than comparable messages passed on by comparable celebrities but authored by ordinary users. The vast majority – 79 percent – of the endorsement effect therefore comes from celebrities speaking in their own voice.

Celebrities also may choose to bolster their credibility by explicitly citing sources, and one may expect this to be particularly important in a public health context, such as vaccines, where celebrities are speaking on subjects far from their own expertise. We find, perhaps surprisingly, that citing sources actually reduces message diffusion. The magnitudes are substantial: randomly attaching a source to a tweet reduces the probability of retweets by 27 percent.

Taken together, our estimates allow us to decompose the celebrity effect: we estimate that 56 percent of the celebrity effect comes from authorship, 14 percent from endorsement, with the remainder attributable to the intrinsic interest of the message. The results suggest that celebrities can play an important role in the diffusion of public health messages, but to do so, they need to speak in their own voice.

Given that people seem to pay attention to the campaign online – liking and retweeting celebrity messages on immunization – we then turn to whether such a campaign has effects on real-world beliefs, knowledge, and behavior. To study this, we used the timing of the tweets to randomly generate differences in exposure to our campaign. Specifically, we randomized the celebrities into two groups, with the first group assigned to tweet during July and August 2015 (Phase I) and the second group assigned to tweet from November 2015 - February 2016 (Phases II and III). We conducted a phone survey of a subset of followers of our celebrities

in between these two groups of tweets. Since we know which of our celebrities each of these followers followed at baseline, this randomization into two phases generates random variation in how many immunization-related tweets from our campaign each individual had potentially been exposed to as of the time of our survey.

The evidence using this variation suggests that exposure to celebrity endorsements of public health messages can have effects. We find that people did pay attention: a one standard deviation increase in exposure to the campaign due to our randomization, equivalent to about 15 tweets or retweets showing up on a user’s Twitter feed over a period of about one month, corresponds to a 20 percent increase in the probability that the respondent in the phone survey knows about our hashtag, #AyoImunisasi; an 11 percent increase in the probability they have heard about immunization through Twitter; and a 14 percent increase in the number of times they report having heard about immunization through Twitter.

We show that exposure to the campaign may have increased knowledge about immunization. We asked phone respondents a number of factual questions about immunization (e.g., whether the vaccine was domestically produced, an important public message for the Government as domestically produced vaccines are known to be halal and hence allowed under Muslim law), all of which were addressed in some of the campaign tweets. A one standard deviation increase in exposure to the campaign corresponds to a 12 percent increase in the probability that the respondent knows that vaccines are domestic (on a base of 58 percent in knowledge in the whole sample) – a key Government message this period to help increase confidence in vaccines, and one that was featured in the Twitter campaign – though we find no increase in the three other dimensions of knowledge we examined.

We then turn to respondents’ knowledge of immunization behavior among neighbors, friends, and relatives. Again we find effects of the celebrity pro-immunization campaign: a one standard deviation increase in exposure corresponds to a 23 percent increase in the probability of reporting knowing about one’s neighbors’ recent immunization behavior. We find no increases in knowledge for friends and relatives. The idea that one would learn about immunization decisions of neighbors is consistent with immunization practices in Indonesia, which take place at *posyandu* meetings, staffed by a midwife, that occur each month in each neighborhood (*dusun* or *RW*) of Indonesia (Olken et al., 2014). Finally, we look at changes in reported immunization decisions of respondents and those of their neighbors, friends, and relatives. We find no effects on one’s own immunization decisions, though our statistical power is such that we cannot rule out substantial effects. But casting a wider net, we find that those exposed to the campaign were more likely to report recent immunizations among neighbors, friends, and relatives. In sum, while the estimates in each domain are suggestive, taken together we find consistent evidence that celebrity endorsements actually may affect both offline knowledge about immunization, as well as the knowledge of health status and health-seeking behavior by one’s neighbors, friends, and relatives.

We build on several facets of the literature. First, we build on the recent literature on diffusion of information for public policy (e.g., Katona, Zubcsek, and Sarvary, 2011; Banerjee, Chandrasekhar, Duflo, and Jackson, 2013; Beaman, BenYishay, Magruder, and Mobarak, 2016; Beaman and Dillon, 2018). While this literature has studied the flow of information over social networks, and how network position affects the flow of information, it has typically been silent on what aspects of the message matter. Therefore, we know little about whether a node’s identity *per se*, composition of message, or even including credible citations affects the nature of a diffusion process. Second, we build on the computer science literature on generating online cascades (e.g., Leskovec et al., 2007; Bakshy et al., 2011). Much of this literature suggests seeding messages with many ordinary citizens, as compared to identifying and targeting any particular influencer, but this literature does not generally provide causal evidence on the role of influencers.

Third, an extensive literature has studied celebrity endorsements, primarily in commercial advertising contexts. This literature has looked on the impacts of celebrity endorsements of various commercial products on outcomes such as stock prices (e.g., Agrawal and Kamakura, 1995), sales (e.g., Elberse and Verleun, 2012; Garthwaite, 2014), and brand evaluations, and studying various aspects of the celebrity’s identity (e.g., gender, attractiveness); see Bergkvist and Zhou (2016) for a comprehensive review. Our study is one of the first to study celebrity effects in the online space through a real-world, large-scale field experiment, and the first large-scale field experiment we know of to study public health messaging of any type. Indeed, the only study of a similar magnitude we know of is a marketing study by Gong, Zhang, Zhao, and Jiang (2017), who experimentally vary tweets in China on Sina Weibo about TV programs, randomizing whether these tweets were retweeted by influencers. Our study builds on this by *decomposing* the celebrity effect, identifying the value of authorship *per se* as opposed to relaying others’ messages, and identifying the value of credible sources, i.e., health authorities in a public health context.

Finally, our study is complementary to social media experiments that examine how exposure to differing information – such as extent of governmental funding of non-profits, alternative political ideological information, and novel news topics – affects engagement and discourse on the platform (Bail et al., 2018; King et al., 2017; Jilke et al., 2019). Our work takes the message as fixed and studies the messenger: the celebrity.

The findings of this paper are of substantial, and immediate, policy relevance. To our knowledge, our study is the only one that conducts a large-scale randomized controlled trial that involves some of the most popular individuals in a nation, that randomizes content itself, and that focuses on vaccination take-up. This makes the project of particular relevance in considering what elements matter when designing information campaigns to combat vaccine hesitancy during the COVID-19 crisis.

2. EXPERIMENT

2.1. Setting and Sample. Our study took place in Indonesia in 2015 and 2016. Indonesia is active on social media, ranking third worldwide with 130 million Facebook accounts⁴ in 2020 (about half the population), and ranking eighth with 10.6 million Twitter accounts (about 6.4 percent of the population).⁵

The experiment focused on immunization. At the time, Indonesia was trying to improve immunization as part of its drive towards the Millennium Development Goals, so this was a government priority. A set of 550 tweets was developed in coordination with the Ministry of Health that sought to improve information about immunization. The tweets included information about access (e.g., immunizations are free, available at government clinics, and so on); information about immunization’s importance (e.g., immunizations are crucial to combat child diseases); and information designed to combat common myths about immunization (e.g., vaccines are made domestically in Indonesia, rather than imported). For each tweet, we identified a source (either a specific link or an organization’s Twitter handle). All tweets were approved by the Ministry of Health, and included a common hashtag, #AyoImunisasi (“Let’s Immunize”). Each tweet was written in Indonesian, with two versions—one using formal Indonesian, and one using casual/street Indonesian, to match the written tweeting styles of the participants.

With help from the Indonesian Special Ambassador to the United Nations for Millennium Development Goals, we recruited 37 high-profile Twitter users, whom we denote “celebrities,” with a total of 11 million Twitter followers. These “celebrities” come from many backgrounds, including music stars, TV personalities, actors and actresses, motivational speakers, government officials, and public intellectuals. They have a mean of 262,647 Twitter followers each, with several having more than one million. While these celebrities primarily tweet about things pertaining to their reason for fame, they also comment occasionally on public issues, often passing on sources or links, so tweets about immunization would not necessarily have been unusual.⁶ We also recruited 9 organizations involved in public advocacy and/or health issues in Indonesia with a mean of 132,300 followers each.

In addition, we recruited 1,032 ordinary citizens, primarily Indonesian university students, whom we call “ordinary Joes and Janes”. Their role will be to allow us to have essentially

⁴<https://www.statista.com/statistics/268136/top-15-countries-based-on-number-of-facebook-users/>

⁵<https://www.statista.com/statistics/242606/number-of-active-twitter-users-in-selected-countries/>

⁶For example, three celebrities in our sample (a musician, a TV personality, and a well-known musician’s agent) had recently tweeted about the importance of breakfast, including a link to an article about the health benefits of children’s breakfast; an athlete tweeted about supporting education for young children; and a musician tweeted in support of Asia Against AIDS.

unimportant, everyday individuals compose tweets that are then retweeted by celebrities. Their Twitter profiles are far more typical, with a mean of 511 followers.

Every participant (celebrities and Joes/Janes) consented to signing up with our app that (1) lets us tweet content from their account (13, 23, or 33 times), (2) randomizes the content of the tweets from a large list of 550 immunization tweets approved by the Ministry of Health, and (3) has no scope for editing.⁷ Participants were given two choices: (1) the maximum number of tweets (13, 23, or 33), and (2) a choice of formal or slang language (to better approximate their normal writing style).

2.2. Experimental Design. Our experiment is designed to understand which aspects of social media campaigns are important for disseminating a message. The choices we have at our disposal are (a) the originator of the message (a Joe/Jane or a celebrity), (b) whether the message contains a credible source from a public health authority, and (c) the content of the message. Ex ante it may seem obvious, for instance, that sources are better (after all, the information is more credible) and celebrity involvement is better (after all, for a variety of reasons the information may be viewed as more credible). But thinking carefully about the information sharing process demonstrates that, in fact, the effect of each of these design options is actually theoretically ambiguous.⁸

We focus on two main interventions: (1) whether a tweet was tweeted directly by a celebrity, or tweeted by a Joe/Jane and then retweeted by a celebrity; and, (2) for a subset of tweets, whether the tweet included a credible source (i.e., the source link or referring organization’s Twitter handle).⁹ To ensure everything else was balanced, we also randomized the timing of tweets (which day and what time of day, matching the empirical frequency of local time-of-day of Indonesian tweets), and the content (i.e., which tweet from our pre-prepared bank of approved tweets was tweeted by whom and when).¹⁰ These various randomizations allow us to identify the role of celebrity reach vs. endorsement, as well as the role of celebrity authorship and sourcing. Given that we have only 46 celebrities and organizations, we refrain from investing heterogeneous effects by characteristics of these celebrities.

Randomizing whether a tweet was directly tweeted by a celebrity or retweeted – in combination with the particular way Twitter messages are shown – allows us to decompose the

⁷Celebrities could veto a tweet if they did not want it sent from their account, though this in fact never happened.

⁸Appendix F presents an application of a simple model developed independently by Chandrasekhar, Golub, and Yang (2018) to demonstrate the ambiguity, though certainly other models can be used and this is inessential for the empirical analysis.

⁹A small subset of tweets on topics deemed ‘sensitive’ by the Government always included a source; these are excluded from the analysis of sourcing.

¹⁰Note that in the period we study, a Twitter user saw all tweets and retweets from the users they follow in strict reverse chronological order (i.e., newest tweets appeared first, and so on). Twitter subsequently (in March 2016) applied an algorithm to prioritize the ordering of the tweets, but since in the period we study (July 2015 through February 2016) tweets appeared in strictly chronological order, nothing in our experimental design affects the ordering of tweets in a user’s Twitter feed.

celebrity effects in two ways. First, we use the fact that Twitter messages show the identity of only two people: the originator who wrote the tweet, and the person whom you follow who directly passed it to you (call this person F). Other steps along the chain are omitted. Consider, for example, two chains. One begins with a celebrity (C) tweeting: $C \rightarrow F_1 \rightarrow F_2$. The other begins with an ordinary Jane/Joe, J , tweeting and the celebrity re-tweeting J 's message, i.e.: $J \rightarrow C \rightarrow F_1 \rightarrow F_2$. In the former case, F_2 sees the celebrity's involvement, whereas in the latter case, F_2 does not. This difference is illustrated in Figure 1. We therefore can study the retweet behavior of F_2 s – i.e., followers-of-followers-of-celebrities – across these two cases to identify the endorsement effect premium, i.e., the additional effect of their knowing that C originated the message, holding F_2 's network position fixed.¹¹

Second, we can decompose the endorsement effect to understand the impact of celebrities speaking in their own voice (an ‘authorship’ effect). We use the same experimental variation, but look at behavior of the direct followers of celebrities (F_1 s), who see both the celebrities’ directly-authored tweets and the celebrities’ retweets. The second experimental variation, whether a source was retweeted, allows us to identify source effects directly by following the behavior of the F_1 s.

Finally, to measure offline effects, celebrities were randomized into two phases, with half tweeting in the first phase (Phase I, July and August 2015) and half in the second phase (November 2015 - February 2016, Phases II and III). In addition, towards the end of the last phase, all tweets / retweets by a celebrity were then retweeted by a randomly selected number of Joes/Janes (Phase III). We conducted a survey between phases (August - October 2015) of a subset of followers of our celebrities and we use this between-celebrity randomization to estimate the impact of the Twitter campaign on offline beliefs and behaviors.

2.3. Data.

2.3.1. *Online data.* We collected detailed data via the Twitter Firehose and API. Before the experiment began, in early 2015, we collected a baseline image of the publicly available Twitter network, including the list of followers of any celebrity participating in our study.

On Twitter, followers can take two primary actions: “likes” and “retweets”. Note that retweets do not necessarily imply endorsement of the views of a tweet, whereas likes do. Second, while likes are public (a user can look up which tweets another user has liked, and can look up who has liked a given tweet), likes are not automatically pushed out as tweets to a user’s followers.

For each the of the 672 total tweets originated by our experiment, we tracked each time the tweet was liked or retweeted by any of the over 7.8 million unique users who followed at least

¹¹A challenge is that the F_1 decision to retweet may be endogenous. We discuss this issue in detail in Section 3.1.1, and show that the results are largely similar in the subset of cases where F_1 s were also study participants whom we randomly selected and had retweet exogenously, and hence the sample of exposed F_2 s is identical.

one of the participants in our study. When the tweet was retweeted by a celebrity’s follower, we also scraped all of this follower’s followers and their liking and retweeting behavior.¹² We denote those retweets / likes coming from a direct follower of a celebrity as F_1 events, and those retweets / likes coming from a follower of a follower of a celebrity as F_2 events. We use the distinction between F_1 and F_2 events in more detail in the analysis below. Table 1 reports descriptive statistics.

2.3.2. *Offline data.* To measure whether online conversations led to offline behavioral changes, we conducted a phone survey on a sample of 2,441 subjects, all of whom followed at least one of our study participants on Twitter. These subjects were recruited primarily via ads placed on the Twitter platform. The phone survey was designed to capture information about immunization (including beliefs in some of the various myths our tweets were intended to counteract), immunization history for children in the family and knowledge of recent immunizations of children of close friends, and questions about immunization and Twitter.

To recruit this sample, we advertised with promoted tweets on Twitter a recruitment to participate in a healthcare survey. We specifically targeted the recruitment ads to the 7.8 million unique users who followed participants in our study, with higher rates of ads for women and for individuals who followed more than one study participant. When users came to the website to sign up, we obtained their Twitter handle so that we could link them to the Twitter network. This process resulted in 2,441 total subjects, all of whom we could link to Twitter.¹³ All respondents were surveyed by phone during the endline period; we also contacted a subsample of these respondents (approximately 73 percent) by phone for a baseline survey prior to the beginning of Phase I tweets.

Table 1, Panel B reports demographics of our offline survey sample. To gauge the sample selection in our sample, we also present comparable data from the 2014 wave of the SUSENAS, the annual representative Indonesian national household survey. Relative to the nationally representative SUSENAS sample, we see that our demographic is more urban, slightly younger, and has a similar gender composition.

Panel C reports baseline statistics for beliefs about vaccinations. We see that there is considerable confusion about the nature and value of vaccines. For instance, only 56 percent of individuals thought that vaccines are domestically made (they are), and only 38.5 percent thought that vaccines are free of cost (they are). This suggests substantial room for improvement on immunization knowledge in our study sample.

¹²Since a given user can follow multiple celebrities, the 11 million total followers of celebrities in our sample represents 7.8 million unique users.

¹³Because we had a limited budget, we recruited respondents using the ads until we had exhausted our allocated budget, which resulted in 2,441 subjects, at which point we stopped our recruitment.

2.4. Estimation. We estimate three models. First, to estimate the overall effect of endorsement, we focus on the behavior of followers-of-followers-of-celebrities – i.e., F_2 s – and estimate by Poisson regression, the equation

$$(2.1) \quad E[y_{trcmp} | \mathbf{x}_{trcmp}] = \exp(\alpha \cdot \text{Celeb}_{tcm} + \beta \cdot \log(\text{Followers})_r + \omega_c + \omega_m)$$

where t indexes tweets, r indexes retweeters (i.e., an F_1 who retweeted the tweet t), c indexes celebrities, m indexes the type of message content, and p indexes phase. The variable Celeb_{tcm} is a dummy that takes 1 if the celebrity authored the tweet herself (and hence her identity is visible to F_2), and 0 otherwise (and hence her identity is not visible to F_2). Each observation is a retweet of one of our original tweets, and the dependent variable y_{trcmp} is a count of how many times this retweet was itself either liked or retweeted again by an F_2 . Since y is a count, we estimate a Poisson regression, with robust standard errors clustered at the original tweet (t) level. We control for the log number of followers of F_1 , and for dummies (ω_m) for different types of messages (e.g., dummies for it being about a fact, importance of immunization, etc.). All regressions include celebrity fixed effects (ω_c), which absorb variation in casual/formal style, etc. The coefficient of interest is α , which measures the differential impact of the tweet having been written by the celebrity (as compared to being written by a Joe/Jane) and this being observable to the F_2 deciding whether to retweet.

Second, to decompose the celebrity effect further, we restrict attention to direct followers of the celebrity (F_1 individuals), and estimate

$$(2.2) \quad E[y_{tcmp} | \mathbf{x}_{tcmp}] = \exp(\alpha \cdot \text{Celeb}_{tcm} + \omega_c + \omega_m).$$

We now have one observation per tweet, and look at the number of retweets/likes, retweets, or likes by F_1 s who are distance 1 from the celebrity. We continue to include celebrity (ω_c), and message-type (ω_m) fixed effects. We run an analogous regression replacing *Celeb* with *Source* to study the impact on F_1 behavior of including public health authority sources.

Finally, to examine offline effects, we turn to our phone survey data. We define Exposure to Tweets $_i$ as the number of campaign tweets that i is randomized to see through Phase I (normalized to have standard deviation 1). Potential Exposure $_i$ is the total number of campaign tweets that i could potentially see through the campaign given the celebrities she follows at baseline. The experimental design of randomizing celebrities into phases means that, while individuals i may differ in the number of our celebrities they follow, Exposure to Tweets $_i$ is random conditional on Potential Exposure $_i$.

We therefore run logistic regressions of the form

$$(2.3) \quad f(y_i) = \alpha + \beta \cdot \text{Exposure to Tweets}_i + \gamma \cdot \text{Potential Exposure}_i + \delta' X_i,$$

where y_i is the outcome for respondent i and $f(\cdot)$ is log-odds, i.e., $\log\left(\frac{P(y_i=1|\mathbf{x}_i)}{1-P(y_i=1|\mathbf{x}_i)}\right)$. X are controls, such as the number of celebrities followed by i , the log of the number of followers of

celebrities by i , survey dates, and (in some specifications) demographics and baseline beliefs, selected here and in subsequent regressions by double post-LASSO (Belloni, Chernozhukov, and Hansen, 2014a,b). We report standard errors and p -values clustered at the level of the combination of celebrities followed; further, because of the complex nature of the potential correlation in Exposure to Tweets $_i$ across individuals i induced by partial overlap in which celebrities our survey respondents follow, we present randomization-inference (RI) p -values as well.

3. RESULTS

3.1. Decomposing The Endorsement Effect: Authorship versus Relaying Messages, and Citing Public Health Authorities.

3.1.1. *Measuring the Total Endorsement Effect.* We begin by measuring the size of the endorsement effect, and then decompose it into the value that comes from direct authorship of a message as opposed to a more passive involvement, and examine the value of citing public health officials.

To do so, we begin by examining the behavior of F_2 s, i.e., followers-of-followers. Recall from the discussion above and the illustration in Figure 1 that if the celebrity retweets a message by a Joe/Jane, and this is retweeted by F_1 , F_2 sees the message, sees that it is composed by a Joe/Jane, and knows that F_1 retweeted it. But crucially F_2 does not know that the celebrity had retweeted it: F_2 is likely to be blind to the celebrity’s involvement. On the other hand, if the celebrity had written this tweet herself, this would be visible to F_2 .

We analyze this by estimating equation (2.1). Table 2 presents the results. We have three main outcome variables: (1) whether an agent either liked or retweeted the tweet, (2) whether an agent liked the tweet, and (3) whether an agent retweeted the tweet. Columns 1, 3, and 5 present the results on the full sample for each of these dependent variables.

We see large endorsement effects. Having a celebrity compose and tweet the message relative to having a Joe/Jane compose the message and the celebrity retweet it leads to a 72 percent (0.54 log point) increase in the retweet or like rate (column 1, $p = 0.001$; note that since this is a Poisson model, the coefficients are interpretable as the change in log number of retweets/likes) by followers-of-followers (F_2 s). The results are qualitatively similar for retweets and likes alone—68 percent (0.52 log points) for retweets and 92 percent (0.66 log points) for likes.

These results imply that, holding the content of the tweet constant (since it is randomized across tweets) and holding the F_2 position in the network constant (since they are all

followers-of-followers of the celebrity), having the F_2 be aware of the celebrity’s involvement in passing on the message substantially increases the likelihood that the F_2 responds online.

The results allow us to begin to decompose the reason for retweeting. Specifically, the estimates imply that 63-72 percent¹⁴ of retweets come from the fact that the celebrity is involved (in this case having written the tweet), with the remainder coming from the intrinsic interest in the content of the tweet itself.

We document similar effects of an organization being the originator rather than a Joe/Jane in Table D.1 of Appendix D.¹⁵

There are two main potential threats to identification. First, when we look at F_2 agents, i.e., those who are at distance two from the celebrity, whether a given agent sees a retweet from his or her F_1 s may be endogenous and respond to our treatment, i.e., which F_1 s choose to retweet the message may be directly affected by the fact that the celebrity composed the message. In equation (2.1), we control for the log number of followers of the F_1 who retweeted the message, and hence the number of F_2 s who could potentially retweet it, so there is no mechanical reason for a bias in equation (2.1). But there may nevertheless be a *compositional* difference in which F_1 s retweet it, which could potentially lead to selection bias of which F_2 s are more likely to see the retweet.

To address this issue, in the last phase of the experiment, we added an additional randomization. We use the subset of Joes/Janes who are also F_1 s, and so direct followers of our celebrities. For some of these Joes/Janes, we randomly had their accounts retweet our celebrities’ tweets and retweets in the experiment; that is, we created exogenous F_1 s. For this sample, we can look at how *their* followers – that is, the followers of F_1 Joes/Janes we exogenously forced to retweet a particular tweet – responded as we randomly vary whether the celebrity, an organization, or a Joe/Jane composes the message. We analyze this experiment by estimating equation (2.1) just as we did for the full sample, but here we know that whether an F_2 sees the tweet is exogenous by construction.

Columns 2, 4, and 6 present the results. The point estimates are if anything somewhat larger than in the full sample, and we cannot reject equality. Statistical significance is reduced somewhat (p -values of 0.119, 0.111, and 0.107 in columns 2, 4, and 6 respectively), but the fact that results are broadly similar to the overall effects in columns 1, 3, and 5 suggests that the possible endogenous selection of F_1 s in our full sample is not leading to substantial bias.

The second potential confound comes from the fact that a retweet shows how many times the original tweet has been retweeted or liked when the user views it (see Figure E.1; the number of retweets is next to the arrow, and the number of likes is next to the heart). Since

¹⁴ $\frac{\exp(\alpha)}{1+\exp(\alpha)}$ for coefficient α .

¹⁵ Recall we only have 9 organizations, which reduces the overall instances of such cases, so we relegate this to an appendix. Also, we condition on non-sensitive tweets for this sample.

our treatment assignment affects the retweet count, this itself could spur further changes in the likelihood of retweeting. The same randomization of forced Joe/Jane retweets also helps address this issue, because we randomly varied the number of Joes/Janes we forced to retweet a particular tweet. We find that being randomly assigned one, five, ten, or even fifteen extra retweets makes no impact on the number of F_1 or F_2 retweets that the given tweet faces (see Appendix C, Table C.1).

3.1.2. Decomposing Endorsement: Authorship vs. Passing on Messages of Others. The preceding analysis compared individuals who were effectively randomly blinded to whether a celebrity was or was not involved in the message composition and message passing to estimate an endorsement effect. While celebrity involvement was through authorship in that case, we do not know to what extent *involvement* per se or *authorship* per se mattered.

To decompose this, we can examine the behavior of the direct followers of the celebrities themselves (i.e., F_1 s). For F_1 s, they know the celebrity is involved either way, but the randomization changes whether it was directly authored by the celebrity or retweeted.

We estimate equation (2.2), and present results in Panel A of Table 3. We find that authorship is important: tweets authored by celebrities are 200 percent more likely to be retweeted/liked than those where the celebrity retweets (column 1, $p < 0.001$). An agent who observes a tweet composed by the celebrity rather than a retweet of a Joe/Jane is 120 percent more likely to like it (column 2, $p < 0.001$) and 280 percent more likely to retweet it (column 3, $p < 0.001$).

This fact allows us to further decompose the impacts of celebrities. These estimates imply that 79 percent of the endorsement effect estimated earlier comes from authorship per se. Combining these estimates with those in the previous section suggests that, on net, 56 percent of the celebrity effect comes from authorship, 14 percent from endorsement, with the remainder attributable to the intrinsic interest of the message.

3.1.3. Citing Public Health Authorities. Finally, we examine the impact of citing sources. Every tweet in our databank was paired with a source, but we randomized at the tweet level whether this source was included or not in the tweet. These source citations in our context come in several forms. In some cases, the tweet refers to the website or Twitter handle of a trusted authority who has issued that statement. For example, one tweet says “Polio vaccine should be given 4 times at months 1, 2, 3, 4. Are your baby’s polio vaccines complete? @puskomdepkes” where @puskomdepkes is a link to the Twitter handle of the Ministry of Health (known as *DepKes* in Indonesian). In other cases, explicit sources are cited, with a Google shortened link provided.¹⁶

¹⁶Note that Twitter automatically produces a short preview of the content if the site linked to has Twitter cards set up. There is one non-Google shortened link used when citing IDAI (Ikatan Dokter Anak Indonesia, the Indonesian Pediatric Society).

We re-estimate equation (2.2) at the F_1 level, adding a variable for whether the tweet was randomly selected to include a source.¹⁷ Panel B of Table 3 presents the results.

On average, we find that citing a public health authority reduces the retweet and liking rate by 26.3 percent (-0.306 log points; $p = 0.051$, column 1). We find that both the retweeting rate and liking rate experience broadly similar declines (retweeting declines by 0.318 log points, $p = 0.048$, column 2; liking declines by 0.277 log points, $p = 0.13$, column 3, not significantly different from zero). On net, the results show that when a message is relayed by citing a public health authority, willingness to pass it on downstream, and perhaps liking the message, declines.

3.2. Does Online Discussion Have Offline Effects?

3.2.1. *Did people hear about the campaign?* We next examine whether an online celebrity endorsement campaign can begin to have measurable offline effects. To investigate this, we estimate equation (2.3). We use the fact that our offline survey was conducted between Phases I and II, as described in Section 2, so that conditional on the number of our celebrities a user followed, exposure to our campaign as of the time of the phone survey was randomly assigned.

We begin with what can be thought of as akin to a first-stage in Panel A of Table 4. We ask whether respondents were more likely to have heard of our hashtag (#AyoImunisasi) or heard about immunization discussions from Twitter if they were randomly more exposed to campaign tweets, conditional on their potential exposure.

Column 1 examines whether the respondent heard of #AyoImunisasi (and therefore remembers the exact hashtag) and column 2 examines whether the respondent heard of a discussion of immunization on Twitter.

We find that a one-standard deviation increase in exposure to the campaign (15 tweets) corresponds to a 16.75 percent increase in the probability that the respondent had heard of our hashtag relative to a mean of 7.7 percent (clustered $p = 0.044$, RI $p = 0.107$).¹⁸ Further, a one-standard deviation increase in exposure corresponds to an 8.3 percent increase in the probability they heard about immunization in general from Twitter relative to a mean of 18.1 percent (clustered $p = 0.106$, RI $p = 0.046$).

3.2.2. *Did people then increase their knowledge about immunization facts?* Next we ask whether exposure to the campaign led to increased knowledge about immunization. Our

¹⁷Note that the number of observations is smaller, because some tweets on topics deemed ‘sensitive’ by the Government always included a source, as noted above. We restrict analysis to tweets for which we randomized whether the source was included.

¹⁸Note that the table reports impacts on log-odds; we report marginal effects in the text, which are interpretable as percent increases. For example, the 16.75 percent increase in column 1 corresponds to an increase in 0.197 in log-odds.

survey asks questions about several categories of knowledge. First, we check for knowledge of several common “myths” about vaccination that our campaign tried to cover. In particular, we ask whether people know that vaccines are domestically produced, to combat the common rumor in Indonesia that they contain pig products in production (which would make them unacceptable for Muslims, who represent the vast majority of Indonesia’s population; domestic products are known to be halal). Second, we ask whether they believe that natural alternatives (breastfeeding, herbal supplements, alternative supplements) replace the need for immunization. Third, we ask whether they are aware that typical symptoms (mild fevers or swelling) are to be expected and not a cause for alarm. The second category we ask about is “access” information; in particular, we ask whether they know that it is free to get one’s child vaccinated at government health centers. All of these issues were covered in the campaign.

The fact that we emphasize the role of messages that dispel myths, such as the fact that vaccines are not domestically produced, is echoed in online behavior. In particular, Table B.1 in Appendix B shows that tweets concerning myths diffused more widely than facts that were non-myths, meaning that the exposure would have been more about myth-busting facts. Moreover, myth-dispelling facts comprised 36.7 percent of all tweets and 82.4 percent of all fact-related tweets sent out (i.e., myths compared to other facts).

Table 4, Panel B, presents the results for each of these four categories of information. We find knowledge effects for our most prominent tweet—domestic production (column 1)—though not on rumors about substitutability, side-effects, nor free access (columns 2-4). Seeing 15 campaign tweets in general corresponded to an increase of 5 percent in the probability of correctly answering the domestic question on a base of 57.6 percent (clustered $p = 0.042$, RI $p = 0.028$; if we adjust for the fact that 4 questions are asked using a Bonferroni-style adjustment, these p-values would be 0.168 and 0.112, respectively).

3.2.3. Communication about immunization. We begin by asking whether individuals were more likely to know about what their neighbors, friends, and relatives’ immunization behavior was, which would be a byproduct of offline conversations, to capture the campaign’s effect. We ask about knowledge of immunizations since since June 2015 to capture the period since the start of the campaign. Immunizations in Indonesia take place at monthly *posyandu* meetings, which occur each month in each neighborhood (usually hamlets, or *dusun*, in rural areas, and neighborhoods known as *rukun warga*, or *RW*, in urban areas; see [Olken, Onishi, and Wong \(2014\)](#)), so if knowledge would increase, one might expect it to be the knowledge about immunization practices of ones’ neighbors.¹⁹

Panel A of Table 5 presents the results. Column 1 shows that being exposed to 15 more tweets corresponds to a 5.2 percent increase in the probability of knowing the neighbor’s

¹⁹Note that here the sample is restricted to respondents who know friends, relatives, or neighbors with at least one child (ages 0-5) respectively as this is the relevant set, which reduces the survey sample.

status (clustered $p = 0.004$, RI $p = 0.088$). We do not consistently see significant effects on non-neighbor friends. With relatives the point estimates are comparably large, though the estimates are noisier. In any case, this is also consistent with the idea that for the most part, individuals have a higher rate of knowledge of health status of those they have closer relationships with (e.g., relatives) and that this is unlikely to change.

3.2.4. Did exposure lead to changes in immunization rate? Finally, we ask whether, among those who knew their friends, neighbors, or relatives' immunization behavior, if there is more immunizing behavior since June 2015, when there is more exposure to the campaign? That is, does the campaign appear to change immunization behavior as reported by our survey respondents?

Panel B of Table 5 presents the results, where the dependent variable is whether the respondent knows of anyone among their friends, neighbors, or family who immunized a child since June 2015. We condition the sample when we look at knowledge of immunization among neighbors, friends, and family to those who knew whether the vaccination status of the children of members of these individuals, so this effect is distinct from the effects reported above. We can therefore ask whether exposure to treatment is associated with greater incidence of vaccination take-up among neighbors, friends, and family, conditional on knowledge of their vaccination status.

An important caveat to this table is that knowledge of neighbors', friends', and family members' children's vaccination status itself is affected by treatment (as discussed above). This is particularly true for neighbors. If knowledge is itself affected by treatment, there can be at least two natural interpretations of these results. The first interpretation is that if the increase in reporting one's child's vaccination status to one's friend is unrelated to the actual status itself, then this regression picks up the treatment effect on vaccination itself. The second interpretation is that the treatment causes differential reporting of status to one's neighbors, so those who took up vaccination for their children may be more likely to speak about it. We cannot separate between the two interpretations, but we present the results nonetheless, advising that the estimates are to be interpreted with some caution.

Column 1 shows that when looking at neighbors, an increased exposure by 15 tweets corresponds to a 12.5 percent increase in the number of vaccinations (clustered $p = 0.071$, RI $p = 0.132$) relative to a mean of 0.356. For friends, shown in column 2, we find an increased exposure of 15 tweets corresponds to a 16.0 percent increase in the number of vaccinations (clustered $p = 0.001$, RI $p = 0.071$) relative to a mean of 0.353. Column 3 presents results looking at relatives. An increased exposure by 15 tweets corresponds to a 9.6 percent increase in the number of vaccinations among relatives (clustered $p = 0.159$, RI $p = 0.06$) relative to a mean of 0.314. Finally, column 4 looks at own behavior, and our estimate is not statistically

different from zero. On net, the results in this section are suggestive that an online Twitter campaign can have offline effects on knowledge and, potentially, behavior.

4. CONCLUSION

Celebrities matter, and many organizations - public and private - seek out their endorsement. In the context of public health, these issues have become particularly pressing with COVID-19, where celebrities have been playing a role trying to support public health messaging.

We study how to design a public health campaign to deploy celebrities effectively by conducting a large-scale, online field experiment. In particular, we are able to decompose to what extent celebrity authorship *per se* as opposed to passing on messages of others matters, and to show in particular whether citing public health officials amplifies or reduces these effects. We find the vast majority (79%) of the 70% increase in retweet rate due to celebrity endorsement coming from authorship.

We also find that explicitly referring to public health sources has an adverse effect. This result may seem surprising, since one might expect that a sourced message may be more reliable. There are, however, several possible explanations for this finding. One idea, which is certainly not the only one, is that for an F_1 , passing on a message has both instrumental value (delivering a good message), as well as a signaling value (conveying to followers that the F_1 is able to discern which information is good). This model was developed by the authors in prior work (Chandrasekhar et al., 2018). We develop this model in this context in Appendix F. Other stories are certainly possible as well. At a broader level, these results are consistent with the results on celebrity authorship: messages are most likely to be passed on when they come from the celebrity speaking directly, rather than passing on messages from others.

We also find offline effects: messages are heard, certain beliefs change while others do not, and offline communication about vaccination increases as does reported immunization behavior among respondents' neighbors, friends, and relatives. Specifically, being randomly exposed to only 15 more campaign tweets leads to 10-20% increased awareness. Further, knowledge of the domestic production of vaccines – a key anti-myth message in this context – increases, consistent with anti-myth messages diffusing more than other messages online. At a minimum this exposure leads to increased communication about vaccination among one's neighbors, friends, and relatives leading to greater knowledge of their decisions, with suggestive results suggesting increases in immunization behavior as well.

These findings are applicable in a wide variety of settings, including perhaps in designing information campaigns to encourage vaccination during the COVID-19 crisis pandemic. The key message of our findings is that, in our setting, an effective design includes recruiting

influential agents, like celebrities, to send self-authored messages in their own voice, *without* explicitly citing credible public health sources. This is a striking and unanticipated finding which merits further investigation, and suggests that policymakers ought to conduct agile experiments as they design campaigns recruiting celebrities to combat vaccination indifference and hesitancy.

VARIABLES	(1)	(2)	(3)	(4)
	Logit Domestic	Logit Substitutes	Logit Side-effects	Logit Free
Std. Exposure to tweets	0.120 (0.0591) [0.0424] {.028}	-0.0391 (0.0589) [0.506] {.891}	0.0305 (0.0624) [0.625] {.751}	0.0549 (0.0687) [0.424] {.629}
Observations	2,434	2,440	2,440	2,440
Potential exposure control	✓	✓	✓	✓
Double Post-LASSO	✓	✓	✓	✓
Depvar Mean	0.576	0.527	0.486	0.680

Notes: Standard errors (clustered at the combination of celebs followed level) are reported in parentheses. Clustered p -values are reported in brackets. Randomization inference (RI) p -values are reported in braces. Demographic controls include age, sex, province, dummy for urban area and dummy for having children. One standard deviation of exposure is 14.96 tweets.

TABLE 5. Communication With and Behavior of Neighbors, Friends, and Relatives

Panel A: Communication: Knowledge of immunization behavior of others

VARIABLES	(1) Logit Neighbor	(2) Logit Friend	(3) Logit Relative
Std. Exposure to tweets	0.231 (0.0814) [0.00449] {.088}	0.0156 (0.0826) [0.850] {.778}	0.214 (0.132) [0.105] {.462}
Observations	1,642	1,626	1,564
Potential exposure control	✓	✓	✓
Double Post-LASSO	✓	✓	✓
Depvar Mean	0.775	0.813	0.923

Panel B: Immunization behavior of others and self

VARIABLES	(1) Logit Neighbor	(2) Logit Friend	(3) Logit Relative	(4) Logit Own
Std. Exposure to tweets	0.194 (0.107) [0.0707] {.132}	0.246 (0.0955) [0.00994] {.071}	0.140 (0.0997) [0.159] {.06}	-0.0840 (0.0886) [0.343] {.66}
Observations	682	682	682	634
Potential exposure control	✓	✓	✓	✓
Double post-LASSO	✓	✓	✓	✓
Depvar Mean	0.356	0.353	0.314	0.486

Notes: In both panels, standard errors (clustered at the combination of celebs followed level) are reported in parentheses. Clustered p -values are reported in brackets. Randomization inference (RI) p -values are reported in braces. Demographic controls include age, sex, province, dummy for urban area and dummy for having children. One standard deviation of exposure is 14.96 tweets. In Panel A, the sample is restricted to respondents who know friends/relatives/neighbors with at least one child (ages 0-5) respectively. In Panel B, the sample when looking at network members' behaviors (columns 1-3) is restricted to respondents who know the behavior of their network. When looking at own behavior in column 4, sample restricted to respondents with children younger than age 2.
