The Effects of Altitude on Soccer Match Outcomes[*]

Tyler Williams and Christopher Walters

August 11, 2011

Abstract

Soccer teams regularly compete at altitudes above 2,000 meters (6,562 feet) with World Cup qualification or other honors on the line. Media, fans, and players often question the fairness of playing at high altitudes, and FIFA temporarily banned international matches above 2,500 meters (8,200 feet) in 2007. Researchers agree that traveling to higher or lower altitude can harm athletic performance, but the effects on professional athletes may be too small to influence match outcomes. Additionally, many teams try to limit altitude effects by allowing players extra time to acclimatize before a match. To identify the causal impact of altitude change, we compare South American international match outcomes between the same teams but played at different altitudes within the same country. This approach controls for influences such as differences in travel distance for high and low altitude countries. We find that traveling to lower altitude does not affect performance but traveling to higher altitude has negative effects. In particular, away teams perform poorly in Quito, Ecuador (2,800 meters), and La Paz, Bolivia (3,600 meters). However, away teams do relatively well in Bogot, Colombia (2,550 meters). We conclude that stadium altitudes should not be restricted under 3,000 meters without further justification.

1 Introduction

In 2007, the Fédération Internationale de Football Association (FIFA) announced a ban on international soccer matches above 2,500 meters (8,200 feet) unless the away team had adequate time to acclimatize. This limit prohibited Bolivia, Colombia, and Ecuador from hosting some matches in their capital cities. The South American soccer federation CONMEBOL and most of its member countries quickly fought back; 47 year old former star Diego Maradona even played in an exhibition against a side headed by Bolivian President Evo Morales at 3,600 meters in La Paz to prove that high altitudes could be overcome. Under heavy pressure, FIFA suspended the ban in May, 2008.

During this period, FIFA held a conference to discuss the impacts of altitude on soccer team performance. The conference participants agreed that altitude change impacts the behavior of a kicked ball and has negative effects on physical performance (Bärstch et al., 2008). The primary negative effects of traveling up are aerobic, due to lower oxygen levels at high altitude, but acute mountain sickness can cause devastating effects, even at 4,000 meters or lower. To achieve peak physical capacity, most participants recommended that soccer players spend one to two weeks acclimatizing before matches above 2,000 meters and at least two weeks acclimatizing before matches above 3,000 meters (Bärstch et al., 2008). Scientific studies also suggest that traveling to lower altitude can harm performance (Gore et al., 2008). Despite this consensus, negative physiological effects could be small for professional athletes within reasonable altitude ranges. Acclimatization procedures such as those recommended by the FIFA conference can also mitigate negative effects of traveling up.

FIFA has primarily been interested in whether high altitude matches are fair; to inform this debate, we investigate whether altitude change has any measurable impact on team performance. We analyze match outcomes from more than 100 years of international soccer in South America, where matches are played at altitudes ranging from sea level to over 4,000 meters. Using similar data, Gore et al. (2008) find that teams traveling either up or down win less often than teams that do not change altitude. These results imply fairness concerns with playing at any altitude - concerns that perhaps balance out. However, the estimates may be biased since there are no controls for characteristics of the away teams. In fact, another study that controls for team characteristics and environmental factors using 10 years of recent South American data finds no effect of altitude change on away team performance (Chumacero, 2009). Using a longer time series, we compare matches between the same home and away teams but played at different altitudes within the host country. This approach holds all team-specific factors constant while allowing altitude to vary; any remaining disparities in match outcomes should be attributable to altitude differences.

We find that traveling down has no impact on match outcomes, but traveling up has a negative, linear effect on away team performance on average. We explore these results further by comparing matches between the same teams played at low and high altitude in Bolivia, Colombia, and Ecuador, country by country. FIFA's initial upper altitude limit was just below Colombia

and Ecuador's main stadium altitudes, so these comparisons are policy relevant. Teams play worse in Ecuador when they must travel up to Quito (2,800 meters), but they actually play better when traveling up to Bogotá (2,550 meters) to play Colombia. Visiting teams' effectiveness at altitude against Colombia suggests that FIFA does not need to cap altitude in the 2,500 to 3,000 meter range. Teams struggle mightily when traveling up to 3,600 meters in La Paz, Bolivia (rather than playing at 400 meters in Santa Cruz), but we refrain from making policy recommendations at this altitude level since our analysis relies on a single country.

2   Data and Results

The match data for this study come from the Rec.Sport.Soccer Statistics Foundation archive (Appendix A lists copyrights and source links). This archive has score and match location data for all international matches played by the top ten South American countries from 1902 to 2009: Argentina, Bolivia, Brazil, Chile, Colombia, Ecuador, Paraguay, Perú, Uruguay, and Venezuela. We exclude neutral site matches. We obtained city latitudes and longitudes in order to link the match data to precise GPS altitude data. If a geographically large city had multiple altitudes in the database, we took the average altitude. To calculate altitude differences for the away team, we compare the away team's capital city altitude to the match altitude, except in the case of Brazil. For Brazil, we use Rio de Janeiro's altitude instead of Brasilia, since Brazil plays most matches in Rio de Janeiro.

Using FIFA data, Gore et al. (2008) estimated the following ordinary least squares regression model:

$$W_i = \alpha + \gamma' H_i + \beta_1 I_i + \beta_2 I_i^2 + \varepsilon_i, \tag{1}$$

where W_i is a dummy for a home win, H_i is a vector of dummies for the home team, and I_i is the increase in altitude for the away team (negative if the team traveled down). The authors approximate the match altitude with each country's main stadium altitude. This regression yields a positive and statistically significant coefficient on the square of the altitude increase. The coefficients imply that traveling up 2,000 meters has little impact on match outcomes, but an away team increase of 4,000 meters increases home team winning percentage by about 8 percentage points. The authors also infer that an away team decrease of 4,000 meters increases home team winning percentage by about 27 percentage points.

Table 1 replicates these results for the 1,551 matches in our data, using the exact altitude for every match. As in the previous study, we estimate that the square of the away team's altitude increase has a statistically significant positive effect on win probability (column 1). We compute effects of altitude change on home goals, away goals, and the score differential in columns 2 through 4, with similar results. The estimates confirm that our data do not differ substantially from the FIFA data, but this regression is likely biased due to differences between away teams that travel up or down. For example, this statistical approach attributes differences in Bolivia

and Argentina's performances in Brazil entirely to altitude change, even though Bolivia and other high altitude countries have performed worse in all settings historically. Any away team characteristics (such as team quality, travel distance, and financial resources) that are correlated with altitude change and with match outcomes will bias the estimated altitude effects.

In table 2, we include a full set of interactions between home and away team dummy variables. Effects from this specification tell us whether altitude changes influence matches between the same home and away team. For example, this approach compares match outcomes between Ecuador and Brazil played in Quito, Ecuador (2,800 meters), versus Guayaquil, Ecuador (sea level). In this comparison, the home and away teams are the same, and Brazil faces similar travel requirements, so we can attribute any disparity in match outcomes to the altitude difference. We drop 277 matches from the data because some pairs of teams always play at the same altitude.

The estimates in panel A of table 2 provide evidence that traveling up or down has little influence on match outcomes. The quadratic effects are of the same sign as in table 1 but they are much smaller and estimated less precisely. The only marginally significant result is the effect of the squared altitude increase on goal differential (column 4). The positive sign on this coefficient implies that teams traveling up or down lose by more goals than teams that do not change altitude, but the effect is not large enough to generate a significant effect on winning or losing (column 1).

These results suggest that altitude changes are not very important, but there may still be specification error. A quadratic form artificially forces the effects of traveling up or down to be on the same curve. In panel B of table 2, we estimate separate linear effects of traveling up or down as follows:

$$W_i = \alpha + \gamma'(H_i * A_i) + \beta_1(I_i * \mathbb{1}[I_i > 0]) + \beta_2(-I_i * \mathbb{1}[I_i < 0]) + \varepsilon_i. \tag{2}$$

Here, β_1 is the effect of traveling up and β_2 is the effect of traveling down, which is estimated independently. The $H_i * A_i$ term represents the interactions between home and away team dummies.

Column 1 of panel B in table 2 shows that home team winning percentage increases by over 5 percentage points for each 1,000 meters that the away team must climb (statistically significant at the one percent level). Effects on goals scored in columns 2 through 4 also suggest large negative effects of traveling up, although they are not estimated precisely. Traveling down has no statistically significant impact on match outcomes.

These results provide evidence of an altitude advantage. However, curvature or discontinuities could still bias the two-sided linear specification. Climbing 1,000 meters is probably not enough to generate a 5 percent increase in home winning percentage, while climbing 4,000 meters might change winning percentage by even more than 20 percent. Estimating separate quadratic functions for traveling up and down would increase flexibility further, but within-country altitude does not vary enough to fit such functions precisely. Instead, we perform simple, non-parametric

"high versus low" comparisons on matches played in Bolivia, Colombia, and Ecuador.[1]

In all three countries, a substantial number of matches are played at high altitude and near sea level. Figure 1 shows that, in Bolivia and Ecuador, teams that climbed at least 2,000 meters for a match fared much worse than teams that did not. Both countries won over 50 percent of their home matches against climbing teams (mostly in La Paz and Quito) but only around 30 percent of their matches against teams that did not climb (mostly in Santa Cruz and Guayaquil). However, Colombia shows the opposite pattern, winning just 45 percent against climbing teams (mostly in Bogot) but 57 percent against teams that did not climb (mostly in Barranquilla).

In Table 3, we show that these simple comparisons hold when controlling for home and away team characteristics. We run a separate regression for each country, capturing the altitude effects with a dummy equal to one if the away team climbed over 2,000 meters. Panel A includes away team dummies to control for biases due to team quality (as in Table 2).[2] Panel B adds controls for each team's yearly winning percentage in low altitude games to capture changes in team quality over time.[3]

The two panels in Table 3 show nearly identical results. Forcing the away team to climb boosts Bolivia's winning percentage by 45 percentage points and Ecuador's winning percentage by 25 to 30 percentage points (both effects significant at the one percent level). Colombia's winning percentage drops by about 20 percentage points when teams must climb to Bogotá. The effect for Colombia is not statistically significant but, at minimum, it implies that Colombia does not gain an advantage from playing at high altitude.

3   Conclusions

Using a two-sided linear regression model on over 100 years of match data, we find that home teams have a distinct advantage in South American international soccer when away teams travel up for a match. In contrast with previous work with similar data (Gore et al., 2008), we control for away team quality and find that traveling down has no impact on match outcomes. Country-specific analysis shows that away teams have had success playing Colombia at an altitude of 2,550 meters, even when controlling for team quality. However, Ecuador's winning percentage increases by 25 to 30 percentage points when they play just 250 meters farther up in Quito. The altitude advantage is even larger at 3,600 meters in Bolivia (45 percentage points). Future work should consider whether the 250 meters between Colombia and Ecuador or other aspects of home field advantage can explain these differences. We rule out strategic scheduling as an explanation by controlling for yearly low-altitude winning percentage.

Away teams' success at over 2,500 meters in Colombia should give FIFA pause when considering an altitude restriction under 3,000 meters. Although Bolivia appears to have a strong

---

[1] We focus on traveling up since FIFA has primarily looked at whether altitude increases hurt performance.

[2] There is no need to interact the away team dummies here, since there is only one home team in each regression.

[3] In particular, we worried that Bolivia, Colombia, and Ecuador schedule games at high altitude when the away team is having a strong year (or they themselves are having a weak year) to increase their chances of winning. Without yearly team quality controls, such strategic scheduling could bias altitude effects downwards.

advantage at 3,600 meters, we advise looking at these results in detail and collecting more data before using them to justify a limit over 3,000 meters. Our statistical findings do not take ethical arguments into consideration, either. High altitude is part of many countries' culture, and other environmental factors remain largely unregulated (e.g., temperature, humidity, and air quality). Altitude does seem to generate an advantage, but any restriction must take all of these factors into account.
