The Macroeconomics of Narratives

Abstract

We study the macroeconomic implications of narratives, or beliefs about the economy that affect decisions and spread contagiously. Empirically, we use natural-language-processing methods to measure textual proxies for narratives in US public firms’ end-of-year reports (Forms 10-K). We find that: (i) firms’ hiring decisions respond strongly to narratives, (ii) narratives spread contagiously among firms, and (iii) this spread is responsive to macroeconomic conditions. To understand the macroeconomic implications of these forces, we embed a contagious optimistic narrative in a business-cycle model. We characterize, in terms of the decision-relevance and contagiousness of narratives, when the unique equilibrium features: (i) non-fundamental business cycles, (ii) non-linear belief dynamics (narratives “going viral”) that generate multiple stable steady states (hysteresis), and (iii) the coexistence of hump-shaped responses to small shocks with regime-shifting behavior in response to large shocks. Our empirical estimates discipline both the static, general equilibrium effect of narratives on output and their dynamics. In the calibrated model, we find that contagious optimism explains 32% and 18% of the output reductions over the early 2000s recession and Great Recession, respectively, as well as 19% of the unconditional variance in output. We find that overall optimism is not sufficiently contagious to generate hysteresis, but other, more granular narratives are.

1 Introduction

At least since Keynes (1936), economists have hypothesized that waves of “spontaneous optimism” generate business cycles. But what drives these fluctuations in beliefs and how much do they matter? The *Narrative Economics* of Shiller (2017, 2020) postulates that contagious stories and worldviews, or “narratives,” induce such movements in beliefs and underlie macroeconomic events. However, the business-cycle relevance of economic narratives, and even their precise meaning, remain unclear.

In this paper, we study how movements in narratives drive aggregate fluctuations in beliefs and output. We first develop a conceptual framework in which we define narratives as subjective models of the macroeconomy that are potentially incorrect. By altering beliefs, narratives influence economic actions like hiring and investment (they are decision-relevant). Moreover, narratives can feed into themselves and gain or lose prevalence over time, in two distinct but complementary ways: direct feedback from their prevalence (they are contagious), as in epidemiological models, and indirect feedback from the economic activity that narratives induce (they are associative), as in models of learning.

We next introduce empirical strategies to test narratives’ decision-relevance, contagiousness, and associativeness at the microeconomic level. We apply several natural-language-processing methods to measure textual proxies for narratives in the universe of 10-K regulatory filings, in which all US public firms discuss “perspectives on [their] business results and what is driving them” (SEC, 2011). We find that measured narratives predict hiring and investment and that their spread depends on both narrative prevalence and economic outcomes at the aggregate and industry level. Moreover, we find that measured narrative optimism predicts over-optimism in sales forecasts and does not correlate positively with future firm productivity growth, stock returns, or earnings growth. Thus, we interpret textual optimism as a narrative that shifts beliefs while being unrelated to future fundamentals.

To understand the importance of these results, we adopt a “micro-to-macro” approach by embedding narratives in a business-cycle model and quantifying its theoretical predictions by using our empirical estimates. We show theoretically that optimistic narratives can lead to non-fundamentally driven boom-bust cycles and hysteresis. Conditional on calibrating standard preference and technological parameters, our empirical estimates point-identify the dynamic macroeconomic effects of narratives. Quantitatively, we find that aggregate fluctuations in narrative optimism account for approximately 32% and 18% of the output reductions over the early 2000s recession and Great Recession, respectively. We therefore argue that contagious narratives may be a first-order determinant of the business cycle.
Measuring Narratives. We first empirically evaluate the two premises of our framework: narratives’ decision-relevance and their contagiousness and associativeness. To this end, we combine data on US public firms’ adoption of textual narratives, using firms’ 10-K filings and earnings call transcripts, and their decisions, using data from Compustat.

Our first method for measuring textual proxies for narratives computes the intensity of positive and negative sentiment using the 10-K-specific dictionary introduced by Loughran and McDonald (2011). We interpret this measure as capturing overall optimism. This measure, which will be our main focus, connects our work to a large literature that studies waves of optimism and pessimism at the aggregate level, without measuring how optimism shapes economic decisions or spreads at the microeconomic level (see e.g., Beaudry and Portier, 2006; Lorenzoni, 2009; Angeletos and La’O, 2013; Benhabib, Wang, and Wen, 2015).

To complement our study of narrative optimism, we apply two other techniques to measure more granular narratives. Our first such technique computes the similarity between firms’ language and the language that best characterizes the Perennial Economic Narratives introduced by Shiller (2020) using a method that has also been applied in Hassan, Hollander, Van Lent, and Tahoun (2019) and Flynn and Sastry (2022). These “narratively identified narratives” are motivated by the historical evidence of relevance and contagiousness provided by Shiller (2020). Our second granular technique estimates a Latent Dirichlet Allocation (LDA) model (Blei, Ng, and Jordan, 2003), which extracts an underlying set of topics, probability distributions over words, based on the frequency with which certain words co-occur within documents. Since we recover these “topic narratives” via an unsupervised method, they allow the data to speak flexibly about what narratives are prevalent among firms without restricting the issues to which narratives may pertain.

Empirical Results. We first provide descriptive evidence about our estimated narratives. Across the three methods, almost all of our estimated narratives are persistent and cyclical. However, it is difficult to ascertain the relationship between narrative and macroeconomic dynamics from the time series alone. This is because narratives potentially serve dual roles of describing true economic fundamentals and encoding non-fundamental beliefs. This challenge for time-series analysis motivates our strategy of testing the two premises of narrative macroeconomics—that narratives are decision-relevant and that they spread contagiously and associatively—at the microeconomic level.

Using our panel data, we first test the decision-relevance of our measured narratives. We focus initially on optimism. We find that optimistic firms, defined as firms with above-median sentiment, hire 3.6 percentage points more than pessimistic firms in a given year, net of firm and sector-time fixed effects. This finding is robust to accounting for firm-level productivity and financial conditions. Moreover, we find that optimism is uncorrelated
with future productivity growth and \textit{negatively} correlated with future stock returns and profitability. These findings are inconsistent with the hypothesis that optimism predicts hiring only because it captures positive firm-level fundamentals (or news thereof). Further, we show using managerial guidance data from IBES that optimism in language predicts negative errors in sales forecasts, or over-optimistic beliefs.

We therefore interpret the association of textual optimism with hiring as arising from non-fundamental, narratively driven, and optimistic beliefs. To underscore this interpretation, we show that changes in optimism driven by plausibly exogenous changes in CEOs (\textit{i.e.}, those caused by death, illness, personal issues, or voluntary retirement of an incumbent CEO, as coded by Gentry, Harrison, Quigley, and Boivie, 2021) lead to quantitatively similar effects on hiring. Finally, we study the relevance of the Perennial Economic Narratives and our estimated topics. Because these narratives are high-dimensional and may not be relevant for firm decisions, we use the Rigorous LASSO method of Belloni, Chernozhukov, Hansen, and Kozbur (2016) for estimating their effects on hiring. We find that two of the nine Perennial Economic Narratives and eleven of the one hundred topics are relevant for hiring.

Second, we study how our measured narratives spread across firms over time. Focusing on optimism, we find that greater aggregate optimism and higher aggregate real GDP growth are associated with a greater probability that a firm is optimistic in the following year—\textit{that is}, in our language, optimism is contagious and associative. We also find evidence of contagiousness and associativeness at the industry level when we control for aggregate conditions with time fixed effects. Moreover, both these aggregate and industry-level results are robust to controlling for future idiosyncratic and aggregate economic conditions. This finding is inconsistent with the explanation that aggregate optimism drives future optimism through its correlation with omitted positive news about measured economic conditions.

By using lagged aggregate optimism in a panel setting, our estimates are not threatened by the reflection problem of Manski (1993). Nevertheless, common shocks that are not spanned by measured aggregate and industry-level conditions may generate omitted variables bias. To address this concern, we employ strategies based on using idiosyncratic shocks to large firms (the granular IV approach of Gabaix and Koijen, 2020) and the aforementioned plausibly exogenous changes in CEOs as instruments for aggregate and industry-level optimism. We find qualitatively consistent effects. Finally, we perform similar analyses for the other decision-relevant narratively-identified and topic narratives. We find that almost all of them are contagious and that many are associative.

**Model.** Having provided microeconomic evidence about narratives’ decision-relevance, contagiousness, and associativeness, we now study their macroeconomic implications. To do this, we embed narratives in an otherwise standard Neoclassical business-cycle model with dis-
persed information à la Angeletos and La’O (2010, 2013). The consumption, production, and labor supply side of the model is a real variant of the standard Neoclassical model of Woodford (2003) and Galí (2008). In particular, the model features aggregate demand externalities (Blanchard and Kiyotaki, 1987), which generate a motive among firms to coordinate the levels of their production. Unlike the aforementioned models, in which firms have correctly specified and rational expectations, our model features narratives that generate heterogeneous and incorrect prior beliefs about the state of aggregate productivity. In our main analysis, we specialize to a case with two narratives: optimism and pessimism. The evolution of narratives is governed by the probabilities that optimists and pessimists remain and become optimistic, respectively, as a function of aggregate output (associativeness) and the fraction of optimists in the population (contagiousness). This allows the model to accommodate the narrative dynamics that we estimated in the data.

**Theoretical Results.** We next derive analytical results that characterize how narratives can generate non-fundamental fluctuations in aggregate output, hysteresis, and boom-bust cycles. We first establish that there is a unique equilibrium in which aggregate output is log-linear in aggregate productivity and a non-linear function of the fraction of optimists in the population. In the case of unanimous optimism, the contribution of optimism equals the partial-equilibrium effect of optimism on one firm’s hiring, as we measured empirically, times a general-equilibrium multiplier. This is because optimism matters both directly for firms and indirectly through aggregate demand externalities. In this way, movements in aggregate optimism lead to non-fundamental fluctuations in aggregate output.

We next describe the dynamics of narratives and output. For a fixed level of aggregate productivity, while there always exists a steady-state level of optimism and equilibrium is unique, there may nevertheless be multiple steady-state levels of optimism. We provide a necessary and sufficient condition for a particularly extreme type of this steady-state multiplicity: if the decision-relevance, contagiousness, and associativeness of narratives are sufficiently strong, then unanimous optimism and unanimous pessimism are both stable steady states. Moreover, depending on the initial fraction of optimists, the economy is (almost everywhere) globally attracted to one of these extreme steady states. In this way, narratives can generate hysteresis: depending on how many optimists there are initially, optimism can either catch on forever (“go viral”) or die out entirely.

We finally study how the economy evolves in response to shocks. Responses to unanticipated “MIT shocks” can fall into three qualitative regimes. If a shock is small, it has a fully transitory impact on aggregate output, because it fails to seed a new narrative. If a shock is medium-sized, it has potentially hump-shaped effects on aggregate output, because it seeds a new narrative that briefly persists before dying out. If a shock is large, it has a permanent
effect on aggregate output, because it makes a narrative “go viral.” Studying stochastic
behavior, we show that the economy oscillates between extreme optimism and pessimism
and provide analytical upper bounds on the expected period of these oscillations. Both
the possibility of these effects and their quantitative magnitudes depend on key measurable
parameters: the decision-relevance, associativeness, and contagiousness of narratives.

Quantification. In the final part of the paper, we calibrate our model to quantify the
extent to which fluctuations in narrative optimism explain historical business cycle fluct-
uations and understand the extent to which narrative dynamics generate hysteresis. In
point-identifying the model, we leverage the fact that our empirical estimates identify both
the partial equilibrium effects of narratives on hiring and the nature of narrative diffusion.

We first study the extent to which narratives generate non-fundamental fluctuations
in output. We find that measured aggregate movements in optimism account for 32% of
output loss during the early 2000s recession and 18% during the Great Recession. More
systematically, we find that optimism accounts for 19% of output variance, and 34% of the
short-run (one-year) and 81% of the medium-run (two-year) autocovariance in output.\footnote{Normatively, we show that contagious optimism can be welfare-improving even if it is unfounded. Quan-
titatively, we find that optimism is welfare-improving and welfare-equivalent to a 1.3% production subsidy.}

We next study the potential for narratively driven hysteresis. For optimism, we quanti-
tatively reject the theoretical condition required for hysteresis in both optimism and output
dynamics. But we do not reject this condition for other narratives, implying that it is possible
for these narratives either to die out or “go viral” depending on initial conditions.

Finally, we study a variant model which allows multiple latent narratives to form a basis
for overall optimism, to evaluate Shiller’s (2020) hypothesis that many narratives may be
mutually reinforcing. We find that the interaction of many simultaneously evolving, granular,
and highly contagious narratives can underlie stable fluctuations in aggregate optimism.

Related Literature. We relate to an empirical literature that measures narratives fol-
lowing Carroll (2001) and Shiller (2017).\footnote{See Carroll and Wang (2022) for a review of the literature on “epidemiological” models of expectations
formation that are centered around social interactions.} Of most relevance, Andre, Haaland, Roth, and
Wohlfart (2022) use surveys to understand narratives underlying inflation, Goetzmann, Kim,
and Shiller (2022) analyze narratives about financial crashes in news media, Macaulay and
Song (2022) study how news coverage of specific narratives affects sentiment on social media,
and Bybee, Kelly, Manela, and Xiu (2021) apply LDA to the full text of Wall Street Journal
articles to extract narrative time series. Our approach differs in its use of text data about
the cross-section of firms to extract narratives, uncover their effects on decision-making, and
study their spread. Our empirical analysis therefore relates to a literature studying the re-

1

5
relationship between firm-level outcomes and their language (Loughran and McDonald, 2011; Hassan, Hollander, Van Lent, and Tahoun, 2019; Hassan, Schreger, Schwedeler, and Tahoun, 2021; Handley and Li, 2020). In contrast to these papers, we calibrate a model to match our firm-level findings and study their general-equilibrium consequences.3

Our work relates to a literature that studies business cycles through time variation in agents’ beliefs. First, our work relates to papers which postulate that the economy undergoes exogenous shocks to demand via news, noise, sentiment, or extrapolation, in theory (Lorenzoni, 2009; Angeletos and La’O, 2010, 2013; Benhabib, Wang, and Wen, 2015; Benhima, 2019; Caballero and Simsek, 2020) and in quantitative applications (Beaudry and Portier, 2006; Christiano, Ilut, Motto, and Rostagno, 2008; Angeletos, Collard, and Dellas, 2018; Bhandari, Borovička, and Ho, 2019; Maxted, 2020; Huo and Takayama, 2022).4 Our work micro-founds such shocks via the endogenous evolution of narratives and corresponding degree of optimism, develops methods to measure agent-level sentiment via textual analysis, and shows how to use microeconomic evidence to quantify their macroeconomic implications.

Second, our modeling of narratives and their spread relates to the work of Carroll (2001), Burnside, Eichenbaum, and Rebelo (2016), and Shiller (2017), in which beliefs spread contagiously between agents. At the same time, our approach differs as we explicitly model narratives and provide microeconomic evidence about narratives’ decision-relevance and spread.5

Finally, in studying the dynamics of misspecified models, we relate to a large macroeconomics and theory literature on model misspecification and learning (see e.g., Marcet and Sargent, 1989a,b; Brock and Hommes, 1997; Esponda and Pouzo, 2016; Acemoglu, Chernozhukov, and Yildiz, 2016; Adam, Marcet, and Beutel, 2017; Molavi, 2019; Bohren and Hauser, 2021). This literature primarily characterizes the limit points of agents’ models. Instead, we study short-run fluctuations and time variation in the models held by agents. This approach is similar to that of Kozlowski, Veldkamp, and Venkateswaran (2020), but we differ in our non-Bayesian and analytical, rather than computational, approach.

**Outline.** The rest of the paper proceeds as follows. In Section 2, we develop our general framework. In Section 3, we describe our data and measurement. In Section 4, we detail our empirical strategy and results. In Section 5, we introduce our macroeconomic model with contagious narratives. In Section 6, we provide theoretical results on macroeconomic dynamics. In Section 7, we quantify the role of narratives. Section 8 concludes.

---

3Flynn and Sastry (2022) and Song and Stern (2021) share this approach of contextualizing the effect of language-based variables on firm-level outcomes in a macroeconomic model.

4Bordalo, Gennaioli, Shleifer, and Terry (2021) and Bordalo, Gennaioli, Kwon, and Shleifer (2021) respectively study how extrapolation can generate credit cycles and speculative bubbles.

5Thus, our model also differs from recent theoretical work in which models correspond to likelihoods (Schwartzstein and Sunderam, 2021) or directed acyclic graphs (Spiegler, 2016; Eliaz and Spiegler, 2020).
2 Narratives: A Conceptual Framework

We first describe a conceptual framework that formalizes the two premises of the macroeconomics of narratives: that narratives are decision-relevant and that narratives spread contagiously and associatively. We embed these two premises in an abstract game in which narratives form the building blocks of agents’ beliefs and agents care about their own actions, fundamentals, and aggregates of other agents’ actions. This game nests our later macroeconomic model in Section 5. We then derive two regression equations that allow us to test the decision-relevance, contagiousness, and associativeness of narratives. We bring these regressions to the data in Section 4 and show that they obtain exactly in our macroeconomic model in Section 6.

2.1 Narratives and Beliefs

We begin by formally defining narratives and how they map into agents’ beliefs. There are random aggregate fundamentals \( \theta \in \Theta \). For example, these fundamentals might represent aggregate productivity or the strength of demand. An individual narrative is a model of fundamentals. We describe each narrative, indexed by \( k \in K \), as a probability distribution \( N_k \in \Delta(\Theta) \) within the set of narratives \( \mathcal{N} = \{N_k\}_{k \in K} \). For example, if the fundamental \( \theta \) describes the strength of productivity, then a pessimistic narrative \( N_P \) might correspond to the view that “productivity in the economy is low,” while an optimistic narrative \( N_O \) may represent the view that “productivity in the economy is high.”

Agents combine narratives to form priors about the fundamental by placing a vector of weights \( \lambda = \{\lambda_k\}_{k \in K} \in \Lambda \subseteq \Delta(K) \) on each narrative. An agent with narrative weights \( \lambda \) has an induced prior distribution over fundamentals given by the following linear combination of distributions in \( \mathcal{N} \):

\[
\pi_\lambda(\theta) = \sum_{k \in K} \lambda_k N_k(\theta)
\]

Continuing the example, an agent who is fully pessimistic might place weight \( \lambda_P = 1 \) on the pessimistic narrative and complementary weight \( \lambda_O = 0 \) on the optimistic narrative, so their subjective probabilities for each state \( \theta \) are \( \pi(\theta) = N_P(\theta) \). An agent who has been convinced by neither narrative might take a middle ground and consider both equally likely, which we would represent with \( (\lambda_P, \lambda_O) = (\frac{1}{2}, \frac{1}{2}) \) or beliefs \( \pi(\theta) = \frac{1}{2} N_O(\theta) + \frac{1}{2} N_P(\theta) \).

The management and organizational literature also views narratives as forming a common set of stories that underpin beliefs (see, e.g., Isabella, 1990; Maitlis, 2005; Loewenstein, Ocasio, and Jones, 2012; Vaara, Sonenshein, and Boje, 2016). Relatedly, Acemoglu and Robinson (2021) postulate that culture arises from the combination of latent cultural attributes. By microfounding the process by which cultural attributes combine, our analysis could be applied to this context.
2.2 Premise I: Narratives are Decision-Relevant

The first premise of the macroeconomics of narratives is that narratives are decision-relevant. To model this, we introduce a continuum of agents indexed by \( i \in [0, 1] \) whose beliefs are formed from narratives, as described above, and who make decisions at a sequence of time periods \( t \in \mathbb{N} \).

These agents care about their own actions \( x_{it} \in \mathcal{X} \), aggregate outcomes \( Y_t \in \mathcal{Y} \), the fundamental state \( \theta_t \in \Theta \), and an idiosyncratic preference shifter \( \omega_i \in \Omega \). They have utility functions \( u : \mathcal{X} \times \mathcal{Y} \times \Theta \times \Omega \to \mathbb{R} \) and information sets \( I_{it} \). Given their information sets, agents update each narrative belief by applying Bayes’ rule and then form their posterior by placing their narrative weights on the updated narrative beliefs. Given a conjecture about the mapping from fundamental states to aggregates \( \hat{Y}_t : \Theta \to \mathcal{Y} \), the agents maximize their expected utility given narrative weights \( \lambda_{it} \) and information \( I_{it} \):

\[
\max_{x_{it} \in \mathcal{X}} \mathbb{E}_{\pi_{\lambda_{it}}} \left[ u(x_{it}, \hat{Y}_t(\theta_t), \theta_t, \omega_i) \mid I_{it} \right] \tag{2}
\]

We linearize these best replies to obtain the following regression equation that allows us to test for the decision-relevance of narratives (see Proposition 6 in Appendix A.1 for the formal arguments):\(^7\)

\[
x_{it} = \gamma_i + \chi_t + \sum_{k \in \mathcal{K}} \delta_k \lambda_{k, it} + \varepsilon_{it} \tag{3}
\]

In this equation, \( \gamma_i \) captures time-invariant factors (preference shifters), \( \chi_t \) captures time-varying aggregate variables such as fundamentals or the overall prevalence of narratives, the \( \delta_k \) correspond to the appropriately normalized expectation of both fundamentals and endogenous aggregate outcomes under narrative \( k \), and \( \varepsilon_{it} \) corresponds to noise around these expectations caused by differences in the information sets across agents. The hypothesis that narratives are decision-relevant is that \( \delta_k \neq 0 \) for some \( k \in \mathcal{K} \). To test this hypothesis in panel data on firms, we will use firm hiring as the relevant outcome and textual measures of narrative adoption as proxies for \( \lambda_{k, it} \), the belief weights in the model. An analog of this equation will hold in equilibrium without approximation in our theoretical model in Section 5, facilitating the use of our estimates for model calibration.

\(^7\)There we also provide assumptions sufficient to guarantee a quadratic misspecification bound and show that \( \varepsilon_{it} \) is mean zero and independent from \( \gamma_i, \chi_t, \) and \( \lambda_{it} \). This latter point implies that, modulo issues of misspecification, the \( \delta_k \) can be estimated consistently via OLS.
2.3 Premise II: Narrative Spread Is Contagious and Associative

We now formalize the second premise: that narratives spread contagiously and associatively. The extent of narrative penetration is summarized by the cross-sectional distribution of narratives in the population, \( Q \in \Delta(\Lambda) \). This represents the distribution of agents’ distributions of narrative weights. For example, in an economy populated by only optimists \( \lambda^O = (0, 1) \), pessimists \( \lambda^P = (1, 0) \) and moderates \( \lambda^M = (\frac{1}{2}, \frac{1}{2}) \), we would have that \( Q = (Q^O, Q^P, Q^M) \) corresponds to the fraction of the population with each combination of weights over optimism and pessimism.

The evolution of the distribution of narratives over time is described by an updating rule \( P : \Lambda \times Y \times \Delta(\Lambda) \rightarrow \Delta(\Lambda) \), which returns the probabilities \( \{P_{\lambda'}(\lambda, Y, Q)\}_{\lambda' \in \Lambda} \) that an agent with narrative weights \( \lambda \) changes their weights to \( \lambda' \) when the endogenous state is \( Y \) and the distribution of narratives in the population is \( Q \).\(^8\) Hence, conditional on a distribution of narratives at time \( t \) given by \( Q_t \) and realized endogenous outcomes given by \( Y_t \), the next period’s distribution of narratives is:

\[
Q_{t+1, \lambda'} = \sum_{\lambda \in \Lambda} Q_{t, \lambda} P_{\lambda'}(\lambda, Y_t, Q_t) \tag{4}
\]

At this level of generality, the updating function can capture Bayesian updating by agents given some latent information structure. However, we can also model behavioral phenomena such as associative learning where agents associate certain states of the economy with certain models (e.g., “aggregate output is high, therefore productivity is high”), and contagiousness, wherein the distribution of narratives itself affects updating.

We linearize the narrative updating equations to obtain the following system of linear probability models (see Proposition 7 in Appendix A.1 for the formal arguments):

\[
P[\lambda_{it} = \lambda | \lambda_{i,t-1}, Y_{t-1}, Q_{t-1}] = \zeta_{\lambda} + \sum_{\lambda' \in \Lambda} u_{\lambda', \lambda} P[\lambda_{i,t-1} = \lambda'] + r_{\lambda} Y_{t-1} + s_{\lambda} Q_{t-1} \tag{5}
\]

Here, \( u \) captures agents’ stubbornness in updating (i.e., their proclivity not to update), \( r \) captures associativeness in updating (i.e., their association of outcomes with a direction of updating), and \( s \) captures contagiousness in updating (i.e., the direct influence of peers’ narrative weights). The hypotheses that narratives are contagious and associative correspond, respectively, to \( s_{\lambda} \neq 0 \) and \( r_{\lambda} \neq 0 \) for some \( \lambda \in \Lambda \). Again, we will use panel data on textual narrative adoption to test these hypotheses. Equation 5 is generated without approximation in the special case of our theoretical model in Section 5 that we study quantitatively.

\(^8\)In Appendix B.6, we extend this setting to allow for idiosyncratic fundamentals and updating that depends on their realizations.
3 Data, Measurement, and Descriptive Statistics

We now describe how we develop a panel dataset on firms’ narrative loadings and decisions. We measure textual proxies for narratives by applying several natural-language-processing techniques to two corpora of language: the universe of public firms’ SEC Forms 10-K and a large sample of earnings calls. We combine these measures of narratives with data on firm fundamentals and choices. Finally, we provide descriptive facts regarding the time-series and cross-sectional properties of narratives.

3.1 Data

**Text.** Our main source of firm-level textual data is SEC Form 10-K. Each publicly traded firm in the US submits an annual 10-K to the SEC. These forms provide “a detailed picture of a company’s business, the risks it faces, and the operating and financial results of the fiscal year.” Moreover, “company management also discusses its perspective on the business results and what is driving them” (SEC, 2011). This description is consistent with our notion that agents’ narratives constitute a view of the world and its rationalization via some model.

We download the universe of SEC forms 10-K from the SEC Edgar database from 1995 to 2019. This yields a corpus of 182,259 html files comprising the underlying text of the 10-K, various formatting information, and tables. We describe our exact method for processing the text data in Appendix C.1. The three key steps are pre-processing the raw text data to isolate English-language words, associating words with their common roots via lemmatization, and fitting a bigram model that groups together co-occurring two-word phrases. We then count the occurrences of all words, including bigrams, in all documents to obtain the bag-of-words representation (i.e., a vector of word counts) for each document.9 Our final sample consists of 100,936 firm-by-year observations from 1995 to 2018.

As an alternative source of text data, we use public firms’ sales and earnings conference calls. Our initial sample consists of 158,810 documents from 2002 to 2014. We apply the same natural-language-processing techniques that we employ for the 10-Ks to this corpus. We average variables over the periods between successive 10-Ks to obtain a firm-by-fiscal-year dataset. Our final sample consists of 25,589 firm-by-year observations. We describe more details in Appendix C.2.

9Other machine-learning approaches use, as input, the entire document instead of its bag-of-words representation. Examples include Doc2Vec, as recently employed by Goetzmann, Kim, and Shiller (2022) to study crash narratives, and RELATIO, which was recently developed by Ash, Gauthier, and Widmer (2021). We view integrating these methods into our analysis as an interesting avenue for future study.
**Firm Fundamentals and Choices.** We compile our dataset of firm fundamentals and choices using Compustat Annual Fundamentals from 1995 to 2018. This dataset includes information from firms’ financial statements on employment, sales, input expenses, capital, and other financial variables. We apply standard selection criteria to screen out firms that are very small, report incomplete information, or were likely involved in an acquisition. We also ignore firms in the financial and utilities sectors due to their markedly different production and/or market structure. More details about our sample selection are in Appendix D.1.

We organize firms into 44 industries, which are defined at the NAICS 2-digit level, but for Manufacturing (31-33) and Information (51), which we split into the 3-digit level. To study narrative transmission at a finer level, we also define peer sets for the subset of firms traded on the New York Stock Exchange using the method of Kaustia and Rantala (2021). These authors exploit common equity analyst coverage to define peers for each firm.\(^\text{10}\)

To measure total factor productivity, we estimate a constant-returns-to-scale, Cobb-Douglas, two-factor production function in materials and capital, for each industry. We estimate the output elasticities using the ratio of materials expenditures to total sales and an assumed revenue returns-to-scale of 0.75. More details are provided in Appendix D.2. We denote our estimated log-TFP variable as \(\log \hat{\theta}_{it}\).

**Manager and Analyst Beliefs.** We collect data from IBES (the International Brokers’ Estimate System) on quantitative sales forecasts by companies and their equity analysts. Specifically, we use the IBES Guidance dataset which records, for specific variables, both (i) a numerical management expectation recorded from press releases or transcripts of corporate events and (ii) a contemporaneous consensus value from equity analysts. We restrict to the first recorded forecast per fiscal year of that year’s sales. When managers’ guidance is reported as a range, we code a point-estimate forecast as the range’s midpoint. We construct two variables from these data at the level of firms \(i\) and fiscal years \(t\). The first, \(\text{GuidanceOptExAnte}_{it}\), is an indicator of managers’ guidance exceeding the analyst consensus. The second, \(\text{GuidanceOptExPost}_{it}\), is an indicator of managers’ guidance minus the realization (both in log units) exceeding the sample median.\(^\text{11}\)

### 3.2 Measurement: Recovering Narratives from Language

We employ three techniques to measure textual narratives at different levels of granularity.

---

\(^{10}\)Firm \(j\) is a peer of firm \(i\) at time \(t\) if they have more than \(C\) common analysts, where \(C\) is chosen so that the probability of having \(C\) or more common analysts by chance is less than 1% when analysts following firm \(i\) randomly choose the firms they follow among all firms with analysts in period \(t\).

\(^{11}\)This method corrects for the fact that, in more than half of our observations, guidance is lower than the realized value, presumably due to asymmetric incentives.
Sentiment Narratives. We first measure firms’ narrative sentiment. We categorize individual words as either positive or negative using the dictionaries constructed by Loughran and McDonald (2011). These dictionaries adjust standard tools for sentiment analysis to more precisely score financial communications, in which certain words (e.g., the leading example “liability”) have specific definitions. We first define $W_P$ as the set of positive words and $W_N$ as the set of negative words. For reference, we print the 20 most common words in each set in Appendix Table A1. We calculate positive and negative sentiment as:

$$
\text{pos}_{it} = \sum_{w \in W_P} \text{tf}(w)_{it} \quad \text{neg}_{it} = \sum_{w \in W_N} \text{tf}(w)_{it}
$$

where $\text{tf}(w)_{it}$ is the term frequency of all bigrams including word $w$ in the time-$t$ 10-K of firm $i$. We then construct a one-dimensional measure of net sentiment, $\text{sentiment}_{it}$, by computing the across-sample $z$-scores of both positive and negative sentiment and taking their difference. Finally, we define a firm $i$ as being optimistic at time $t$ if its sentiment is above the entire-sample median:

$$\text{opt}_{it} = I[\text{sentiment}_{it} \geq \text{med (sentiment}_{it})]$$

This variable has a simple interpretation in capturing optimistic narratives, but necessarily collapses more fine-grained discussion of specific topics.

Narrative Identification of Narratives. To measure more specific narratives entertained by firms, we next consider a supervised strategy based on narratively identifying a set of narratives using the text of Shiller’s Narrative Economics. Shiller identifies a set of nine Perennial Economic Narratives: Panic versus Confidence; Frugality versus Conspicuous Consumption; The Gold Standard versus Bimetallism; Labor-Saving Machines Replace Many Jobs; Automation and Artificial Intelligence Replace Almost All Jobs; Real Estate Booms and Busts; Stock Market Bubbles; Boycotts, Profiteers, and Evil Businesses; and The Wage-Price Spiral and Evil Labor Unions. Each of these narratives and its history is described in its own chapter in Narrative Economics. We measure narrative adoption by computing the similarity between each 10-K filing and the relevant chapter of the book.

Formally, we use a method related to prior work by Hassan, Hollander, Van Lent, and Tahoun (2019) and our own implementation in Flynn and Sastry (2022). For each narrative $k$, we first compute the term-frequency-inverse-document-frequency (tf-idf) score to obtain

---

12Loughran and McDonald (2011) generate the dictionaries based on human inspection of the most common words in the 10-Ks and their usage in context. We describe more details of our document scoring methodology in Appendix C.3.
a set of words most indicative of that narrative:

\[
\text{tf-idf}(w)_k = \text{tf}(w)_k \times \log \left( \frac{1}{\text{df}(w)} \right) \tag{8}
\]

where \(\text{tf}(w)_k\) is the number of times that word \(w\) appears in the chapter corresponding to narrative \(k\) in *Narrative Economics* and \(\text{df}(w)\) is the fraction of 10-K documents containing the word. Intuitively, if a word has a higher tf-idf score, it is common in Shiller’s description of a narrative but relatively uncommon in 10-K filings. We define the set of 100 words with the highest tf-idf score for narrative \(k\) as \(W_k\). For reference, we print the twenty most common words in each set \(W_k\) in Appendix Table A2.

Finally, we score document \((i,t)\) for narrative \(k\) by the total frequency of narrative words:

\[
\hat{\text{Shiller}}^k_{it} = \sum_{w \in W_k} \text{tf}(w)_{it} \tag{9}
\]

We compute loadings on each narrative, \(\hat{\text{Shiller}}^k_{it}\), by taking the z-score. These variables measure a set of more specific topics, but rely on Shiller’s specific wording of narratives.

**Unsupervised Recovery of Narratives.** Finally, to identify narratives without relying on any external references, we use Latent Dirichlet Allocation (LDA), a hierarchical Bayesian model in which documents are constructed by combining a latent set of topic narratives (Blei, Ng, and Jordan, 2003). More specifically, given our corpus of 10-Ks with \(M\) documents, we postulate that there are \(K = 100\) topics. First, the number of words in each document is drawn from a Poisson distribution with parameter \(\xi\). Second, the distribution of topics in each document is given by \(\vartheta = (\vartheta_1, \ldots, \vartheta_M)\), over which we impose a Dirichlet prior with parameter \(\alpha = \{\alpha_k\}_{k \in K}\), where \(\alpha_k\) represents the prior weight that topic \(k\) is in any document. Third, the distribution of words across topics is given by \(\phi = (\phi_1, \ldots, \phi_K)\), over which we impose a Dirichlet prior with parameter \(\beta = \{\beta_{jk}\}_{k \in K}\), where \(\beta_{jk}\) is the prior weight that word \(j\) is in topic \(k\). Finally, we assume that individual words in each document \(d\) are generated by first drawing a topic \(z\) from a multinomial distribution with parameter \(\vartheta\), and then selecting a word from that topic by drawing a word from a multinomial distribution with parameter \(\phi_z\). Intuitively, in an LDA, the set of documents is formed of a low-dimensional space of narratives of co-occurring words.

To estimate the LDA, we use the *Gensim* implementation of the variational Bayes algorithm of Hoffman, Bach, and Blei (2010), which makes estimation of LDA on our large dataset feasible, when standard Markov Chain Monte Carlo methods would be slow.\(^{13}\) Given

\(^{13}\)For computational reasons, we estimate the model using all available documents from a randomly sampled 10,000 of our 37,684 unique possible firms. We score all documents with this estimated model.
Figure 1: Aggregate Time Series for Six Selected Narratives

Notes: Optimism is measured as the fraction of optimistic firms. The other five time series are cross-sectional averages of z-score transformed variables (zero mean, unit standard deviation).

For each of the eleven topics that our subsequent analysis identifies as relevant for hiring (see Section 4.1), we print the ten highest-weight bigrams and their weights in Appendix Table A3. These topics are qualitatively different from the word sets used by our sentiment scoring (Appendix Table A1) and Shiller narratives (Appendix Table A2).

3.3 Descriptive Analysis of Narratives

Before our main empirical analysis, we first describe the time-series and cross-sectional structure of our measured narratives.

Time-Series Properties. In Figure 1, we show the time path of six selected measured narratives: optimism, “Labor-Saving Machines” and “Stock Bubbles” from Shiller’s perennial narratives, and three topics whose three most common terms are “Advertising, Retail, Brand”; “Reorganization, Bankruptcy, Plan”; and “Technology, Revenue, Development.” Our choices among the Shiller chapters and unsupervised topics are among the set that our
later analysis suggests is particularly important for explaining hiring in the cross-section. At a glance, all of these narratives are highly persistent and feature business-cycle fluctuations, and some have notable trends and breaks.\textsuperscript{14} In Appendix Table A4, we report summary statistics for all narratives’ autocorrelation and correlation with unemployment. Almost all measured narratives are persistent, and several among the Shiller and topic sets are pro- or counter-cyclical. This observation is consistent with existing evidence in the literature on the cyclicality of aggregate text-based measures of narratives (\textit{e.g.}, Shiller, 2020) and news coverage (\textit{e.g.}, Baker, Bloom, and Davis, 2016; Bybee, Kelly, Manela, and Xiu, 2021).

However, our framework implies that it is challenging to interpret these basic time-series facts for two reasons. First, it is difficult to disentangle the dual roles of narratives in driving behavior versus describing fundamentals. In the next section, we will use cross-sectional variation in narratives to isolate the impact on behavior.\textsuperscript{15} Second, without an understanding of how narratives affect decisions and how decisions aggregate, it is difficult to understand the macroeconomic implications of even desirable time-series variation in optimism. We will later combine our macroeconomic model with our microeconomic evidence to evaluate the business-cycle impact of aggregate variation in narratives quantitatively.

**Cross-Sectional Properties.** Our firm-level panel allows us to explore variation that is more fine-grained than the time-series variation of Figure 1. We perform a variance decomposition of each narrative variable by comparing the total variance of each variable with the variance after removing means at the time, industry, industry-by-time, and firm levels. In Appendix Table A5, we present the results in units of the fraction of variance explained by each level of fixed effects, relative to the total. Time-series variation constitutes a very small percentage of the total variation in our variables—only 1.1% for optimism, 0.2% for the median Shiller narrative, and 3.5% for the median topic narrative. Adding industry-specific trends increases these percentages, respectively, to only 6.7%, 8.7%, and 9.9%. The vast majority of variation is therefore at the firm level.

4 Empirical Results

Moving beyond descriptive evidence, we now use our dataset of firm-level outcomes and narrative loadings to test the two premises that narratives are decision-relevant and that narrative spread is contagious and associative.

\textsuperscript{14}In the Appendix, we report the time-series plot for Positive Sentiment, Negative Sentiment, and their difference (Figure A1); all nine Shiller (2020) Perennial Economic Narratives (Figure A2); and all eleven LDA topics that our later analysis identifies as relevant for hiring (Figure A3).

\textsuperscript{15}In Table A28 we show that failing to control for aggregate time-series variation leads to an upward bias in the impact of optimism on firms’ hiring, as predicted by the theory.
4.1 Testing Premise I: Narratives Are Decision-Relevant

**Empirical Strategy.** From the conceptual framework in Section 2 (see Equation 3 and Proposition 6 in Appendix A.1), we have that firm hiring $\Delta \log L_{it}$ can be described to first order by the following regression equation:

$$
\Delta \log L_{it} = \sum_{k \in \mathcal{K}} \delta_k \lambda_{k,it} + \gamma_i + \chi_t + \varepsilon_{it} \tag{11}
$$

where the $\lambda_{k,it}$ are firm-specific loadings on narratives indexed by $k$, $\gamma_i$ is a fixed effect spanning static firm characteristics, $\chi_t$ is a fixed effect spanning aggregate conditions (including both fundamentals and the distribution of narratives), and $\varepsilon_{it}$ is a residual term arising from idiosyncratic noise in individuals’ signals.

We first operationalize this by estimating the following regression equation relating hiring to our optimism variable constructed in the 10-Ks:

$$
\Delta \log L_{it} = \delta^{OP} \text{opt}_{it} + \gamma_i + \chi_{j(i),t} + \tau' X_{it} + \varepsilon_{it} \tag{12}
$$

Hiring and optimism are constructed as described in Section 3, at the level of firms and fiscal years. We augment our theoretically implied specification (Equation 11) with controls, including industry-by-time fixed effects and a suite of firm-level time-varying controls $X_{it}$ (current and past TFP, lagged labor, and financial variables). We later estimate analogs of Equation 12 with other estimated narratives as independent variables.

**Main Result: Optimism Drives Decisions.** We present our estimates of Equation 12 in Table 1. We first estimate the model with no additional controls beyond fixed effects and find a point estimate of $\hat{\delta}^{OP} = 0.0355$ with a standard error of 0.0030 (column 1). In column 2, we add controls for current and lagged TFP, and lagged labor ($\log \hat{\theta}_{it}, \log \hat{\theta}_{i,t-1}, \log L_{i,t-1}$). These controls proxy both for time-varying firm fundamentals and, to first order, the presence of adjustment costs in labor.\(^{16}\) Our point estimate $\hat{\delta}^{OP} = 0.0305$ (SE: 0.0030) is quantitatively comparable to our uncontrolled estimate. To formalize this, in Appendix E.1 we report the robustness of our estimate to selection on unobservables using the method of Oster (2019). We find that our finding of a positive effect of optimism on hiring is robust by the benchmark suggested by Oster (2019) (see Table A6).

In column 3, we add measures of firms’ financial characteristics, the (log) book-to-market

\(^{16}\)In Appendix B.9, we show that the controls capture the impact of adjustment costs, to first order, for a forward-looking firm that observes current productivity. This notwithstanding, to evaluate robustness to the presence of richer adjustment dynamics, in Table A7, we control for up to three lags of productivity and labor and our financial controls and continue to find a significant impact of optimism on hiring.

Notes: For columns 1-4, the regression model is Equation 12 and the outcome is the log change in firms’ employment from year $t-1$ to $t$. The main regressor is a binary indicator for the optimistic narrative, defined in Section 3.2. In all specifications, we trim the 1% and 99% tails of the outcome variable. In column 5, the regression model is Equation 13, the outcome is the log change in firms’ employment from year $t$ to $t+1$, and control variables are dated $t+1$. Standard errors are two-way clustered by firm ID and industry-year.

To test if optimism predicts (and does not merely describe) hiring, we finally estimate a specification in which the outcome and control variables are time-shifted one year in advance:

$$
\Delta \log L_{i,t+1} = \delta_{-1}^{OP} \text{opt}_{it} + \gamma' X_{i,t+1} + \gamma_i + \chi_{j(i),t+1} + \varepsilon_{i,t+1}
$$

(13)

where $\delta_{-1}^{OP}$ is the effect of lagged optimism on hiring and the (time-shifted) control variables $X_{i,t+1}$ are those studied in column 2. In this specification, hiring takes place in fiscal year $t+1$ after the filing of the 10-K at the end of fiscal year $t$. Our point estimate in column 5 ratio, last fiscal year’s log stock return (inclusive of dividends), and leverage (total debt over total assets). These controls proxy for both Tobin’s $q$ and firm-level financial frictions. These controls are conservative in that they may absorb variation in both omitted firm fundamentals and optimism itself. The point estimate remains positive and quantitatively similar. In column 4, we estimate a specification with the controls from column 2 but no firm fixed effects to guard against small-sample bias from strict exogeneity violations (Nickell, 1981) and find similar results.\(^{17}\)

\(^{17}\)In Table A8, we report standard errors for the estimates of Table 1 under alternative schemes for clustering standard errors.
is similar in magnitude to our comparable baseline estimate (column 2).\footnote{In Table A9, we report results from our baseline regression Equation 12, using $opt_{i,t-1}$ as an instrument for $opt_{i,t}$. This is robust to any identification concern arising from the simultaneous determination of $opt_{i,t}$ and $\Delta \log L_{it}$, but estimates the original parameter $\delta^{OP}$ rather than $\delta_{-1}^{OP}$. Our estimates are positive, statistically significant, and larger than our baseline estimates.}

**Robustness.** As an alternative strategy to isolate plausibly exogenous variation in the narratives considered by firms, we study the effects on hiring of changes in narratives induced by plausibly exogenous CEO turnover. We provide the details in Appendix E.2. Specifically, we estimate a variant of Equation 12 over firm-year observations corresponding to the death, illness, or voluntary retirement of a CEO, as measured by Gentry, Harrison, Quigley, and Boivie (2021). We find quantitatively similar effects of narrative optimism on hiring as those reported in Table 1.

In the Appendix, we also report several additional results that probe the robustness of our main specification. We summarize them briefly here. First, Figure A4 shows estimates of a variant of our baseline regression interacting optimism with quartiles of firm characteristics. We find that the effect of optimism is decreasing in capital intensity, essentially flat in market capitalization, and U-shaped in the book-to-market ratio (i.e., high for both growth firms and value firms). Second, Table A10 repeats the analysis of Table 1 with our conference-call-based optimism measure, and finds similar results. Third, Table A11 repeats our main analysis for different measured inputs—employment (the baseline), total variable input expenditure, and investment—and demonstrates a positive and comparably sized effect of optimism on all three. Thus, optimism expands operations uniformly across inputs. Finally, we have so far studied the impact of binary optimism on hiring. To check if this construction drives our results, in Figure A5 we re-create the regression models of the first three columns of Table 1 with indicators for each decile of the continuous sentiment measure. We find monotonically increasing associations of hiring with higher bins of sentiment, implying that our binary construction is not masking non-monotone effects of the continuous measure.\footnote{In Appendix E.4, we also check whether the effects of narrative optimism depend on the past level of narrative optimism. We find that there are larger marginal effects on average for recently pessimistic firms, but that this heterogeneity is quantitatively small.}

**Inspecting the Mechanism: Narrative Optimism Does Not Predict Future Productivity Growth, Predicts Negative Stock Returns and Profitability.** The coefficient of interest, $\delta^{OP}$, measures the impact of optimism on hiring if optimism is uncorrelated with any omitted fundamental factors that affect hiring. We have already demonstrated that controlling for firm-level productivity, current labor employed, and financial variables has minimal impact on the estimated value of $\delta^{OP}$. Thus, any correlation between measured optimism and measured contemporaneous and lagged fundamentals does not generate quan-
Figure 2: Dynamic Relationship of Optimism with Firm Fundamentals

Notes: The regression model is Equation 14, and each coefficient estimate is from a different regression. The outcomes are (a) the log change in TFP, calculated as described in Appendix D.2, (b) the log stock return inclusive of dividends, and (c) changes in profitability, defined as earnings before interest and taxes (EBIT) as a fraction of the previous fiscal year’s variable costs. In all specifications, we trim the 1% and 99% tails of the outcome variables. Error bars are 95% confidence intervals, based on standard errors clustered at the firm and industry-year level.

To investigate these issues, we estimate projection regressions of firm-fundamentals \( Z_{it} \), either TFP growth \( \Delta \log \hat{\theta}_{it} \), log stock returns \( R_{it} \), or changes in profitability \( \Delta \pi_{it} \), on optimism at leads and lags \( k \):

\[
Z_{it} = \beta_k \text{opt}_{i,t-k} + \gamma_i + \chi_{j(i),t} + \varepsilon_{it} \tag{14}
\]

For negative \( k \), \( \beta_k \) measures the relationship of current fundamentals with future optimism. For positive \( k \), \( \beta_k \) measures the relationship of current fundamentals with past optimism.

We show our findings graphically in Figure 2, in which each point is a coefficient from a separate estimation of Equation 14 and the error bars are 95% confidence intervals. For \( k < 0 \), and all three outcome variables, we find evidence of \( \beta_k > 0 \)—that is, a firm doing well today in terms of TFP growth, stock-market returns, and/or profitability is likely to become optimistic in the future. However, for \( k > 0 \), and all three outcome variables, we

\[20\text{We measure profitability as earnings before interest and taxes (EBIT) divided by the previous fiscal year’s total variable costs (cost of goods sold (COGS) plus selling, general, and administrative expense (SGA), minus depreciation).} \]
find no positive association—that is, a firm doing well today was not on average optimistic yesterday, or a firm that is optimistic today does not on average do better tomorrow. This is consistent with our required exclusion restriction that our narrative measure of optimism is non-fundamental, and it is inconsistent with a story in which optimism is driven by news about fundamentals.\footnote{To further investigate the effects on stock prices, we also estimate the correlation of optimism with stock returns near the 10-K filing date (Appendix Table A12). We find essentially no evidence of stock response on or before the filing day, and weak evidence of positive returns (about 15-25 basis points) in the four days after. The latter finding is consistent with those in Loughran and McDonald (2011).}

We find, in sharp contrast, that optimistic firms have negative stock returns and decreasing profitability in the future. This is consistent with our finding that optimistic firms persistently increase input expenditure (column 5 of Table 1), but see no increase in productivity (panel (a) of Figure 2). Figures A6 and A7 replicate this analysis with conference-call-based optimism and the continuous measure of net sentiment, respectively, and find similar results.\footnote{Jiang, Lee, Martin, and Zhou (2019) relatedly find that positive textual sentiment in firm disclosures, by their own measure, predicts negative excess returns over the subsequent year.}

This analysis focuses on real, rather than financial, fundamentals. In Figure A8, we investigate the relationship between narrative optimism, leverage, the capital structure, and payout policy. We find that narrative optimism predicts higher leverage and higher borrowing and has no effect on both equity issuance and payouts. Taken together, this provides evidence that narrative optimism is associated with tighter, instead of looser, future financial conditions. This is again inconsistent with a view that narrative optimism drives increases in hiring because it is correlated with positive news about future firm-level financial conditions.

**Inspecting the Mechanism: Narrative Optimism Predicts Optimistic Beliefs.** In our theoretical framework, optimistic narratives increase hiring by increasing firms’ expectations about fundamentals. To test this mechanism, we investigate the relationship between narrative optimism and the extent to which firms make more optimistic forecasts. As described in Section 3.1, we define GuidanceOptExPost\(_{i,t+1}\) and GuidanceOptExAnte\(_{i,t+1}\) to indicate firms’ optimism at the beginning of fiscal year \(t+1\) relative to realized sales and contemporaneous sales forecasts of equity analysts, respectively. For each variable GuidanceOpt\(_{i,t+1}\), we estimate the following regression model:

\[
\text{GuidanceOpt}_{i,t+1} = \beta_{\text{opt}} \cdot \text{opt}_{it} + \tau' \cdot X_{it} + \chi_{j(i),t} + \varepsilon_{it}
\]

The control variables \(X_{it}\) are current and lagged TFP and lagged labor, all in log units. As we have guidance data for only a small subset of firms, we do not include firm fixed effects.

Our findings are reported in Table 2. For optimism relative to realizations, we find a positive correlation that increases when we add the aforementioned control variables (columns...

Notes: The regression model is Equation 15. The outcomes are binary indicators for whether sales guidance was high relative to realized sales (columns 1 and 2) or high relative to contemporaneous analyst forecasts (columns 3 and 4), as defined in Section 3.1. Standard errors are two-way clustered by firm ID and industry-year.

1 and 2). This is consistent with the notion that firms producing an optimistic 10-K truly hold optimistic views about firm performance. For optimism relative to analysts, we find an imprecise positive effect in an uncontrolled model and a zero effect in the controlled model. These findings are consistent with a story in which optimism is shared between management and investors, potentially due to persuasion in communications.23,24

Given that we have found that guidance correlates with narrative optimism, it is natural to ask if narrative optimism affects firm decisions conditional on guidance (and vice versa). In Appendix E.3, we find that narrative optimism and measured expectations each have predictive power conditional on the other for explaining hiring and capital investment. These results suggest that textual optimism captures aspects of managers’ latent beliefs that are not represented in traditional measurement of expectations (here, in guidance data).

The Narratives that Matter for Decisions. We now study the decision-relevance of the measured Shiller (2020) and topic narratives. Specifically, for each of the two sets of narratives, we estimate the regression equation implied by our theoretical framework:

\[ \Delta \log L_{it} = \sum_{k \in K} \delta_k \hat{\lambda}_{k,it} + \gamma_i + \chi_{j(i),t} + \tau' X_{it} + \varepsilon_{it} \]  

23In Table A13, we re-estimate this relationship with alternative measurement schemes. We find a positive relationship between ex post optimism and continuous sentiment, and an insignificant relationship between binary or continuous narrative sentiment with the continuous difference between guidance and realized sales.24Loughran and McDonald (2011) similarly find that, in Fama-MacBeth predictive regressions of standardized unexpected earnings, 10-K negativity predicts higher earnings surprises in the subsequent quarter.

Notes: Each column lists the narrative variables chosen as relevant regressors in a Rigorous Square-Root LASSO (Belloni, Chernozhukov, Hansen, and Kozbur, 2016) estimation of Equation 16, with the baseline controls as unpenalized regressors. The Shiller (2020) chapters are named for the title of the corresponding book chapter. The topics are named after the three highest-weight bigrams. The corresponding post-LASSO estimates are reported in Table A14.

We use our baseline controls, current and lagged TFP and lagged labor. Because we have many candidate narratives (9 and 100, respectively), and we expect only a few to matter for decisions, we apply the Rigorous Square-Root LASSO method of Belloni, Chen, Chernozhukov, and Hansen (2012) and Belloni, Chernozhukov, Hansen, and Kozbur (2016) to estimate the subset of hiring-relevant narratives. In Table 3, we list the selected Shiller (2020) and topic narratives. In Appendix Table A14, we report the post-LASSO OLS estimates of Equation 16 with the selected variables.

Among the Shiller (2020) Perennial Economic Narratives, the LASSO methodology selects two of nine as quantitatively relevant for hiring: “Labor-Saving Machines” and “Stock Bubbles.” Among the unsupervised topics, the LASSO methodology selects eleven variables out of 100. In Table A14, we present these topics in the (essentially random) order they come out of our LDA exercise and identify them by their three highest-weight bigrams (in all cases, single words).

Ex post, based on their word combinations, we identify two as relating to demand conditions (Topics 4 and 7); two related to legal proceedings (Topics 9 and 10); one related to technology development (Topic 11); one related to real estate (Topic 1); and the remaining five related to financial conditions.

Are these selected narratives reasonable? For the Perennial Economic Narratives, we

\[\text{25} \text{ Appendix Table A3 prints the top ten words per topic and their numerical weights.}\]
observe that “The Gold Standard” and “Boycotts and Evil Businesses” describe episodes in history that are unlikely to be relevant over our sample. Our results are therefore consistent with this “placebo test.” There are no analogous tests for the topics, which pertain to the sample period by construction. Instead, we test if topics that seem to describe specific decisions are relevant for those decisions. Concretely, using analogs of Equation 12 to predict other firm-level decisions, we find that the “Advertising, Retail, Brand” narrative predicts SG&A expenditure growth ($\delta = 0.0076$, SE: 0.0022) and that the “Technology, Revenue, Development” narrative predicts growth in R&D spending ($\delta = 0.0402$, SE: 0.0044).

Going further, we examine the relationship of the selected Shiller and topic narratives with narrative optimism in two ways. First, we study if optimism has different effects when it coincides with more intense discussion of other narratives. To do this, for each of the thirteen hiring-relevant Shiller and topic narratives, we take our baseline regression (Equation 12) with controls for lagged labor and current and lagged TFP and add both the non-optimism narrative and its interaction with optimism. Out of our thirteen estimated regressions, the smallest $p$-value for an interaction coefficient that is different from zero is 0.039. Applying a Bonferroni correction for multiple hypothesis testing, we would not reject the null that all interactions are zero at any significance level less than 50%. Thus, we find limited evidence that optimism acts differently when it interacts with other, more specific narratives.

Given the irrelevance of the interaction between optimism and more specific narratives, we next consider the possibility that these narratives form a basis for narrative optimism: that is, emergent overall optimism is driven by discussion of more specific narratives. We estimate the following system of equations in which we treat optimism as an endogenous variable and the LASSO-selected Shiller and topic narratives (in sets $K^*_S$ and $K^*_T$) as instruments:

$$\Delta \log L_{it} = \delta^{op} \text{opt}_{it} + \gamma_i + \chi_{j(i),t} + \tau'X_{it} + \varepsilon_{it}$$

$$\text{opt}_{it} = \sum_{k \in K^*_S} \delta_{S_k} \text{Shiller}_{it}^k + \sum_{k \in K^*_T} \delta_{T_k} \text{topic}_{it}^k + \gamma_i + \chi_{j(i),t} + \tau'X_{it} + \varepsilon_{it}$$

(17)

where $X_{it}$ are, again, our baseline controls. We provide coefficient estimates for Equation 17 in column 4 of Appendix Table A14. The Shiller and topic narratives strongly predict optimism ($F = 189$), and our IV estimate of a 0.0597 log-point effect of optimism on hiring is larger than our baseline estimate of 0.0305.

4.2 Testing Premise II: Contagious and Associative Spread

**Empirical Strategy.** From the conceptual framework in Section 2 (see Equation 5 and Proposition 7 in Appendix A.1), we have that narrative updating is described by a system
of linear probability models that depend on agents’ previous narrative weights, the previous narrative weights of the population, and economic outcomes.

To operationalize this idea in the context of our measured binary optimism, we first estimate the following model:

\[ \text{opt}_{it} = u \text{opt}_{i,t-1} + s \text{opt}_{e,t-1} + r \Delta \log Y_{t-1} + \gamma_i + \epsilon_{it} \]  

(18)

where \( \text{opt}_{e,t-1} \) is average optimism in the previous period, \( \Delta \log Y_{t-1} \) is US real GDP growth, and \( \gamma_i \) is an individual fixed effect. Following our earlier interpretation, \( u \) measures stubbornness, \( s \) measures contagiousness, and \( r \) measures associativeness.

**Main Result: Optimism Spreads Contagiously and Associatively.** In column 1 of Table 4, we show our estimates. We find strong evidence of \( u > 0 \), \( s > 0 \), and \( r > 0 \)—that is, firms are significantly more likely to be optimistic in year \( t \) if, in the previous year, they were optimistic, if other firms were optimistic, and if the economy grew.

Our estimation of Equation 18 levers only the time-series variation over our studied 23-year period. We therefore also study a model that allows for contagiousness and associativeness at the finer levels of our 44 industries and our firm-specific peer groups. Specifically, we estimate the equation:

\[ \text{opt}_{it} = u_{\text{ind}} \text{opt}_{i,t-1} + s_{\text{ind}} \text{opt}_{j(i),t-1} + s_{\text{peer}} \text{opt}_{p(i),t-1} + r_{\text{ind}} \Delta \log Y_{j(i),t-1} + \gamma_i + \chi_t + \epsilon_{it} \]  

(19)

where \( \text{opt}_{j(i),t-1} \) and \( \text{opt}_{p(i),t-1} \) are (leave-one-out) means of optimism among a firm’s industry and peer set, respectively, and \( \Delta \log Y_{j(i),t-1} \) is the growth of sectoral value-added measured by linking Bureau of Economic Analysis (BEA) sector-level data to our NAICS-based classification.\(^{26}\) The time fixed effect \( \chi_t \) absorbs aggregate contagiousness and associativeness.

We show the results in columns 2 and 3 of Table 4. First, using just the industry-level data, we find strong evidence for contagiousness and weaker evidence for associativeness within industries. Second, including the peer set optimism and restricting to the much smaller number of NYSE-listed firms, we find both a quantitatively similar industry-level effect and an independent peer-set effect. Moreover, the sum of coefficients \( s_{\text{ind}} + s_{\text{peer}}, \) the marginal effect of optimism in both the industry and peer set, is positive and strongly significant (estimate 0.243, standard error 0.075). In Table A16, we report evidence of stubbornness, contagiousness, and associativeness with the continuous measure of sentiment and find consistent results, suggesting that our qualitative findings are not unduly sensitive to variable construction.\(^{27}\)

---

\(^{26}\)These data are available only from 1997.

\(^{27}\)In Table A15, we report standard errors for Table 4 under alternative clustering.

Notes: The regression model is Equation 18 for column 1, and Equation 19 for columns 2 and 3. Aggregate, industry, and peer average optimism are averages of the narrative optimism variable over the respective sets of firms. Industry output growth is the log difference in sectoral value-added calculated from BEA data, linked to two-digit NAICS industries. Standard errors are two-way clustered by firm ID and industry-year.

**Inspecting the Mechanism: Spillovers are Not Driven by Common Shocks.** The coefficients of interest, \( u, r, \) and \( s \) identify stubbornness, contagiousness, and associativeness, when idiosyncratic optimism, aggregate optimism, and GDP are unrelated to other factors that affect changes in optimistic sentiment at the firm level. By using lagged aggregate optimism, our estimates are not threatened by the reflection problem of Manski (1993). Nevertheless, our estimates may be contaminated by omitted variables bias because aggregate optimism is correlated with common shocks to the economy that are in the error term.

To test for this possibility, we augment our previous regressions to include controls for past and future fundamentals in the form of two leads and lags of real value-added growth at the aggregate and sectoral levels as well as firm-level TFP growth. Specifically, we estimate

\[
\text{opt}_{it} = u \; \text{opt}_{i,t-1} + s \; \text{opt}_{t-1} + \gamma_i + \\
\sum_{k=-2}^{2} (\eta_k^{\text{agg}} \Delta \log Y_{t+k} + \eta_k^{\text{ind}} \Delta \log Y_{j(i),t+k} + \eta_k^{\text{firm}} \Delta \log \theta_{i,t+k}) + \varepsilon_{it} \tag{20}
\]

</table>

Notes: The regression model is Equation 20 for columns 1-4, and an analogous industry-level specification for columns 5-7 (i.e., Equation 19 with past and future controls). Columns 1 and 5 are “baseline estimates” corresponding, respectively, with columns 1 and 3 of Table 4. The added control variables are two leads, two lags, and the contemporaneous value of: real GDP growth (columns 2-4), industry-level output growth (columns 3-4 and 6-7), and firm-level TFP growth (columns 4 and 7). Standard errors are two-way clustered by firm ID and industry-year.

We estimate an analogous specification at the industry level, but with the aggregate leads and lags absorbed. If common positive shocks to the economy and sectors were driving some or all of the estimated spillovers, we would expect to find a severely attenuated estimate of the contagiousness coefficient \( s \). Even under our interpretation, future output growth could be a “bad control” that is caused by optimism and absorbs some of its effect.

We report our estimates of the contagiousness coefficients in Table 5, adding the “bad controls” one at a time. In column 2 we find that instead of attenuating \( \hat{s} \), controlling for past and future aggregate fundamentals in fact slightly increases the original point estimate reported in column 1 (within one standard error of the original value). In columns 3 and 4, when we additionally control for sectoral-level value-added growth and firm-level TFP growth, the point estimates drop slightly while standard errors increase significantly. Similarly, for our industry-level estimates, we find no statistically significant evidence of coefficient attenuation as additional controls are added (columns 5 to 7). In Table A17, we report analogous estimates with the continuous sentiment variable and find similar results. Taken together, these estimates build confidence that our baseline contagiousness results are not driven by omitted aggregate shocks.

To further test whether our measure of contagiousness captures spillovers, and not omit-
ted common shocks, we pursue two additional instrumental variables strategies. First, in Appendix E.2, we use spillovers from the same plausibly exogenous CEO changes to construct instruments for industry and peer-set optimism. We find similar point estimates as in our main analysis. Second, in Appendix E.5, we use size-weighted idiosyncratic shocks to firm-level optimism as an instrument for aggregate size-weighted optimism (a granular IV à la Gabaix and Koijen, 2020). While not comparable to our main estimates as the measure of spillovers is different, we recover a statistically significant contagiousness effect.

The Spread of Hiring-Relevant Narratives. We repeat the estimation of our equation measuring aggregate associativeness and contagiousness, Equation 18, for the other thirteen narratives that are selected by our LASSO procedure as relevant for hiring. To allow for the greatest comparability with our estimates for optimism, we transform these narrative loadings into binary indicators for being above the sample median. We present our estimates of \( u, r, \) and \( s \) in the three panels of Appendix Figure A9. We find significant evidence of stubbornness, or \( u > 0 \), in each case and significant evidence of contagiousness, or \( s > 0 \), in all but two cases. We find some evidence of associativeness \( (r \neq 0) \) for certain narratives, with “Lease, Tenant, Landlord” (relating to real estate), “Debt, Credit, Facility” (relating to financial conditions and leverage), and “Reorganization, Bankruptcy, Plan” (relating to firm restructuring) having \( r < 0 \), and “Court, Settlement, District” (relating to legal proceedings), “Business, Public, Combination” (relating to firm origination), and “Technology, Revenue, Development” (relating to R&D) having \( r > 0 \). In Appendix Table A18, we instrument for optimism with the other 13 hiring-relevant narratives in the estimation of Equations 18 and 19. We find similar point estimates to our baseline analysis that are suggestive of increased contagiousness.

To assess whether these findings are consistent with our earlier findings about decision relevance, we can test whether the sign and magnitude of associativeness line up across narratives with the sign and magnitude of the hiring effect. That is, do narratives that increase firm hiring also spread more when the economy is growing? While our theory does not impose such a restriction, it might be a natural consequence of the unmodeled process by which narratives pick up associations with aggregate outcomes. In Figure A10, we plot the associativeness coefficients for each narrative (including optimism) against the effect of the corresponding binary variable on hiring. Consistent with our hypothesis, the relationship is upward-sloping, with optimism itself in the top-right corner (with the second-highest hiring effect and highest associativeness).
5 A Narrative Business-Cycle Model

To study the implications of narratives for macroeconomic dynamics, we now specialize our abstract framework and develop a microfounded business-cycle model that embeds the decision-relevance, contagiousness, and associativeness of narratives.

5.1 Technology and Preferences

The consumption, production, and labor supply side of the model is intentionally standard and is a purely real variant of the models described in Woodford (2003) and Gali (2008). Time is discrete and infinite, indexed by \( t \in \mathbb{N} \). There is a continuum of monopolistically competitive intermediate goods firms of unit measure, indexed by \( i \), and uniformly distributed on the interval \([0, 1]\). Intermediate goods firms have idiosyncratic (Hicks-neutral) productivity \( \theta_{it} \). They hire labor \( L_{it} \) monopsonistically at wage \( w_{it} \) to produce a differentiated variety in quantity \( x_{it} \) that they sell at price \( p_{it} \) according to the production function:

\[
x_{it} = \theta_{it} L_{it}^\alpha \tag{21}
\]

where \( \alpha \in (0, 1] \) describes returns-to-scale in production.

A final goods firm competitively produces aggregate output \( Y_t \) by using a constant elasticity of substitution (CES) production function:

\[
Y_t = \left( \int_{[0, 1]} x_{it}^{\frac{\epsilon - 1}{\epsilon - \gamma}} d i \right)^{\frac{\epsilon - 1}{\epsilon - \gamma}} \tag{22}
\]

where \( \epsilon > 1 \) is the elasticity of substitution between varieties.

A representative household consumes final goods \( C_t \) and supplies labor \( \{L_{it}\}_{i \in [0, 1]} \) to the intermediate goods firms with isoelastic, separable, expected discounted utility preferences:

\[
U(\{C_t, \{L_{it}\}_{i \in [0, 1]}\}_{t \in \mathbb{N}}) = E_0 \left[ \sum_{t=0}^{\infty} \beta^t \left( \frac{C_t^{1-\gamma}}{1 - \gamma} - \int_{[0, 1]} \frac{L_{it}^{1+\psi}}{1 + \psi} \, d i \right) \right] \tag{23}
\]

where \( \gamma \in \mathbb{R}_+ \) indexes the size of income effects in the household’s supply of labor and \( \psi \in \mathbb{R}_+ \) indexes their inverse Frisch labor supply elasticity to each firm.

Finally, we define the composite parameter:

\[
\omega = \frac{1}{\frac{1}{\epsilon} - \gamma} - \frac{\alpha}{\alpha + 1} \tag{24}
\]
which indexes the strength of strategic complementarity. So that complementarity is positive but not so extreme that the model features multiple equilibria, we assume that \( \omega \in [0, 1) \). This requires that income effects in labor supply do not overwhelm aggregate demand externalities and that these externalities are not too large.

### 5.2 Narratives and Beliefs

Firm productivity \( \theta_{it} \) is comprised of a common, aggregate component \( \theta_t \), an idiosyncratic time-invariant component \( \gamma_i \), and an idiosyncratic time-varying component \( \tilde{\theta}_{it} \):

\[
\theta_{it} = \tilde{\theta}_{it} \gamma_i \theta_t
\]  

(25)

Firms know that \( \log \gamma_i \sim N(\mu_\gamma, \sigma^2_\gamma) \), know their own value of \( \gamma_i \), and believe that \( \log \tilde{\theta}_{it} \sim N(0, \sigma^2_{\tilde{\theta}}) \) and independently and identically distributed (IID) across firms and time. As in Angeletos and La’O (2010, 2013), firms receive idiosyncratic Gaussian signals about \( \log \theta_t \) with noise \( \epsilon_{it} \sim N(0, \sigma^2_e) \) that is IID across firms and time: \( s_{it} = \log \theta_t + \epsilon_{it} \).

As in the conceptual framework from Section 2, and unlike in previous work, narratives form a common factor structure of agents’ prior beliefs about the aggregate component of productivity \( \theta_t \). To best fit our main empirical analysis, we suppose that there are two competing narratives: an optimistic narrative and a pessimistic narrative. According to each narrative, the aggregate component of productivity follows:

\[
\log \theta_t \sim N(\mu, \sigma^2)
\]  

(26)

where \( \mu = \mu_P \) under the pessimistic narrative and \( \mu = \mu_O > \mu_P \) under the optimistic narrative. Both of these narratives are potentially misspecified, and the true distribution for fundamentals is given by \( H \). In Appendix B.4, we study a variant model in which narratives pertain to beliefs about idiosyncratic productivity and show that our analysis is unchanged.

Firms either believe the optimistic narrative or the pessimistic narrative. Hence, each firm’s prior belief regarding the fundamental can be described as:

\[
\pi_{it}(\lambda_{it}) = N \left( \lambda_{it} \mu_O + (1 - \lambda_{it}) \mu_P, \sigma^2 \right)
\]  

(27)

where \( \lambda_{it} \in \{0, 1\} \), \( \lambda_{it} = 1 \) corresponds to a firm believing in the optimistic narrative, and \( \lambda_{it} = 0 \) corresponds to a firm believing in the pessimistic narrative. We let \( Q_t = \int_{[0,1]} \lambda_{it} \, di \) correspond to the fraction of optimists in the population, which agents observe each period.
5.3 Narrative Evolution

To describe the evolution of narratives, we need to describe the probability that optimists remain optimistic, \( P_O \), and the probability that pessimists become optimistic, \( P_P \). We specify that both probabilities depend on aggregate output \( Y_t \), the fraction of optimists in the population \( Q_t \), and an aggregate narrative shock to how agents update \( \varepsilon_t \), which has distribution \( G \). Hence, the fraction of optimists evolves according to:

\[
Q_{t+1} = Q_t P_O(\log Y_t, Q_t, \varepsilon_t) + (1 - Q_t) P_P(\log Y_t, Q_t, \varepsilon_t)
\]

(28)

This aggregates the behavior of individual firms’ narrative updating. As we found that narratives spread associatively and contagiously (Section 4.2), we assume that \( P_O \) and \( P_P \) are both increasing functions. As we found that firms are stubborn, or that optimism is persistent at the firm level, we assume that \( P_O \geq P_P \). As associativeness and contagiousness do not explain all narrative updating, we add narrative shocks to the probabilities that optimists and pessimists update. Finally, for technical reasons, we assume that \( P_O \) and \( P_P \) are continuous and almost everywhere differentiable.

These conditions, motivated by the data, rule out some models for how individual firms update their beliefs. An important such model that is ruled out is one in which firms observe aggregate variables \( \log Y_t \) and \( Q_t \) and use Bayes’ rule to update their beliefs over models. As we formalize in Appendix B.1, this “Bayesian benchmark” rules out dependence of firms’ updating on \( Q_t \) and \( \varepsilon_t \) conditional on \( \log Y_t \) (respectively, contagiousness and shocks). Moreover, this “Bayesian benchmark” predicts that agents converge to holding the better-fitting empirical model exponentially quickly, which is at odds with our finding of cyclical dynamics for aggregate optimism (Figure 1). However, richer Bayesian models that are consistent with our empirical results can be nested by our reduced-form updating probabilities.

To illustrate our results, obtain closed-form expressions, and exactly match our regressions and quantitative model, we will study the following updating probabilities throughout:

**Main Case** (Linear-Associative-Contagious Updating Probabilities). The linear-associative-contagious (LAC) specification for updating probabilities sets:

\[
P_O(\log Y, Q, \varepsilon) = \left[ \frac{u}{2} + r \log Y + sQ + \varepsilon \right]^1_0
\]

\[
P_P(\log Y, Q, \varepsilon) = \left[ -\frac{u}{2} + r \log Y + sQ + \varepsilon \right]^1_0
\]

(29)

where \( [z]^1_0 = \max\{\min\{z, 1\}, 0\} \), \( u \geq 0 \) indexes stubbornness, \( r \geq 0 \) indexes associativeness, and \( s \geq 0 \) indexes contagiousness. \( \triangle \)
5.4 Equilibrium

An equilibrium is a path for all variables:

$$\mathcal{E} = \left\{ Y_t, C_t, Q_t, \theta_t, \varepsilon_t, \{L_{it}, x_{it}, p_{it}, w_{it}, \lambda_{it}, s_{it}, \tilde{\theta}_{it}\}_{i \in [0,1]} \right\}_{t \in \mathbb{N}}$$ (30)

such that (i) narrative weights $\lambda_{it}$ follow a Markov process consistent with Equation 28 given $Q_t$ and $Y_t$, (ii) $x_{it}$ maximizes intermediate goods firms’ expected profits given their narrative weights $\lambda_{it}$, signal $s_{it}$, and knowledge of $\mathcal{E}$, (iii) $L_{it}$ is consistent with production technology (Equation 21) given $x_{it}$ and $\tilde{\theta}_{it}$, (iv) prices $p_{it}$ are consistent with profit maximization by the final goods firm, (v) wages $w_{it}$ clear the labor market for each firm, (vi) $Y_t$ aggregates intermediate good production according to Equation 22, (vii) $C_t$ satisfies goods market clearing, $C_t = Y_t$, and (viii) $Q_t$ evolves according to Equation 28.

6 Theoretical Results

We now study the equilibrium dynamics of narratives and output. We find that narratives induce non-fundamental fluctuations in the economy and have the potential to generate hysteresis. Moreover, we show that our empirical estimates identify the model. We use this mapping to the data to quantify and test the model’s predictions in Section 7.

6.1 Characterizing Equilibrium Dynamics

To solve for equilibrium production, it suffices to solve for intermediates goods production. These firms maximize expected profits, as priced by the representative household:

$$\Pi_{it} = \mathbb{E}_{it}\left[ C_t^{-\gamma} (p_{it} x_{it} - w_{it} L_{it}) \right]$$ (31)

where $C_t^{-\gamma}$ is the (unnormalized) stochastic discount factor that converts the profits of the firm into their marginal value to the household. The intermediate goods firm acts as a monopolist in the product market and a monopsonist in the labor market.

We first solve for the demand curve faced by the intermediates goods firms. The final goods firm maximizes profits taking as given the prices set by intermediates goods firms. This implies the following constant-price-elasticity demand curve:

$$p_{it} = Y_t^{\frac{1}{\gamma}} x_{it}^{-\frac{1}{\gamma}}$$ (32)

Increases in aggregate output shift out this demand curve via aggregate demand externalities.
Second, we solve for the wage schedule faced by the intermediate goods firm. When facing a wage $w_{it}$, the intratemporal Euler equation of the representative household implies that labor supply is given by:

$$L_{it}^\psi = w_{it}C_t^{-\gamma}$$  \hfill (33)

Third, given the production technology of the firm, when it commits to producing $x_{it}$, its implied labor input is given by:

$$L_{it} = \theta_{it}^{-\frac{1}{\alpha}}x_{it}^{\frac{1}{\alpha}}$$  \hfill (34)

Finally, by imposing goods market clearing $C_t = Y_t$ and substituting Equations 32, 33, and 34 into Equation 31, we obtain that the intermediates goods firms solve the following profit maximization problems:

$$\max_{x_{it}} \mathbb{E}_{it} \left[ Y_t^{-\gamma} \left( Y_t^{\frac{1}{\alpha}}x_{it}^{\frac{1}{\alpha}} - Y_t^{\gamma\theta_{it}^{-\frac{1}{\alpha}}x_{it}^{\frac{1}{\alpha}}} \right) \right]$$  \hfill (35)

By the first-order condition of this program, we have that optimal production solves:

$$\left( 1 - \frac{1}{\epsilon} \right) \mathbb{E}_{it} \left[ Y_t^{\frac{1}{\alpha}-\gamma}x_{it}^{-\frac{1}{\alpha}} = \frac{1 + \psi}{\alpha} \mathbb{E}_{it} \left[ \theta_{it}^{-\frac{1+\psi}{\alpha}}x_{it}^{\frac{1+\psi}{\alpha}} \right] \right]$$  \hfill (36)

where the left-hand side is the marginal expected revenue of the firm from expanding production and the right-hand side is the marginal expected cost of this expansion. In this equation, a given firm’s narrative affects their expected marginal costs of production, via the expectation of idiosyncratic productivity, and their expected marginal benefits of production, via the expectation of aggregate output (which encompasses aggregate demand externalities, asset pricing forces, and wage pressure). Moreover, in equilibrium, the distribution of narratives in the population affects the level of aggregate output and agents’ expectations thereof.

We now take logarithms of all variables, and substitute this best reply into the production function of the final goods firm. From this, we obtain that the static equilibrium of the model is characterized by the solution to the following fixed-point equation:

$$\log Y_t = \frac{\epsilon}{\epsilon - 1} \log \mathbb{E}_{it} \left[ \exp \left\{ \frac{\epsilon - 1}{\frac{1+\psi-\alpha}{\alpha} + \frac{1}{\epsilon}} \left( \log \left( \frac{1 - \frac{1}{\epsilon}}{1 + \psi} \right) \right) \right. \right.$$  

$$- \log \mathbb{E}_{it} \left[ \exp \left\{ - \frac{1 + \psi}{\alpha} \log \theta_{it} \right\} \right] + \log \mathbb{E}_{it} \left[ \exp \left\{ \left( \frac{1}{\epsilon} - \gamma \right) \log Y_t \right\} \right] \left\} \right] \right)$$  

where the outer expectation operator integrates over the realizations of productivity shocks ($\tilde{\theta}_{it}, \gamma_i$), narrative loadings $\lambda_{it}$, and signals $s_{it}$.

By employing a functional guess-and-verify argument, we obtain that the model has
a unique \textit{quasi-linear} equilibrium in which log output depends linearly on log aggregate productivity and non-linearly, but separably, on the fraction of optimists in the population:

\textbf{Proposition 1 (Equilibrium Characterization).} There exists a unique equilibrium such that:

$$\log Y(\log \theta_t, Q_t) = a_0 + a_1 \log \theta_t + f(Q_t)$$ \hspace{1cm} (38)

for some coefficients $a_0$ and $a_1 > 0$, and a strictly increasing function $f$.

\textit{Proof.} See Appendix A.2 \hfill \square

\textbf{Remark 1.} This result claims uniqueness only within the quasi-linear class. As best replies and aggregation are non-linear and the spaces of actions and fundamentals are not compact, one cannot use classical arguments to ensure that the fixed point operator implicit in Equation 37 is a contraction. Nevertheless, in Appendix A.2, we show that there is a unique equilibrium when fundamentals are restricted to lie in a compact set (Lemma 2). Moreover, the claimed quasi-linear equilibrium is an $\varepsilon-$equilibrium for any $\varepsilon > 0$ for some sufficiently large support for fundamentals (Lemma 3). Hence, the quasi-linear equilibrium we study is the limit of the unique equilibrium with bounded fundamentals as the bound becomes large. This justifies our restriction in analyzing this class of equilibrium. \triangle

\textbf{Narratives Drive Non-Fundamental Fluctuations in Aggregate Output.} The coefficient $a_1$ and function $f$ respectively describe how fundamentals and optimism drive aggregate output. In the proof of Proposition 1, we derive these objects as functions of the macroeconomic parameters $(\epsilon, \psi, \gamma, \alpha)$, the signal-to-noise ratio of agents’ signals about productivity $\kappa$, and the extent of mean differences in the priors of optimists and pessimists $\mu_O - \mu_P$. The effect on output from going from full pessimism to full optimism is given by

$$f(1) = \frac{\alpha \delta^{OP}}{1 - \omega}$$ \hspace{1cm} (39)

where $\delta^{OP}$ is the average partial equilibrium effect of a firm being optimistic on hiring, the returns-to-scale parameter $\alpha$ converts this into the effect on production, and $\frac{1}{1 - \omega}$ is the general equilibrium multiplier of this effect.

The role of optimism in equilibrium has two subtle properties. First, the effect of optimism on output, $f(Q)$, is non-linear. The non-linearity arises from the fact that firms’ heterogeneous priors induce heterogeneity in production conditional on productivity and hence also misallocation. Second, there is an equilibrium multiplier for optimism due to demand externalities. In particular, even a pessimistic firm will produce more if a large fraction of other firms is optimistic, as this optimism increases aggregate demand.
Identification of Model Parameters. We now show how our empirical strategy identifies the aggregate behavior of output and optimism.

**Corollary 1** (Identification of Model Parameters). In equilibrium, firms’ hiring decisions obey the following equation:

\[
\Delta \log L_{it} = c_{0,i} + c_1 \log \theta_t + c_2 f(Q_t) + c_3 \log \theta_{it} + c_4 \log L_{it-1} + \delta^{OP} \lambda_{it} + \zeta_{it} \quad (40)
\]

where \( \zeta_{it} \) is an IID normal random variable with zero mean. Thus, conditional on \((\alpha, \epsilon, \gamma, \psi)\), \(\delta^{OP}\) uniquely identifies \(f\), the equilibrium effect of optimism on aggregate output.

*Proof.* See Appendix A.4.

This clarifies the exact interpretation of our regression model for hiring, Equation 12, in the model. The general-equilibrium effect of optimism on hiring, \(c_2 f(Q_t)\), was absorbed in the regression equation as a time fixed effect. As we previously discussed, aggregate fundamentals also appear in the time fixed effect of the regression. These facts highlight formally the necessity of combining cross-sectional variation and some structural model for general-equilibrium interaction to identify the effect of optimism on economic outcomes.

The Dynamics of Optimism. Finally, using Proposition 1, we express the dynamics of the economy as a first-order nonlinear stochastic difference equation for aggregate optimism:

**Corollary 2** (Characterization of Dynamics). Optimism evolves according to the following stochastic, nonlinear first-order difference equation

\[
Q_{t+1} = T(Q_t, \nu_t), \quad \text{where} \quad \nu_t = (\log \theta_t, \varepsilon_t)
\]

and

\[
T(Q_t, \nu_t) = Q_t P_O (a_0 + a_1 \log \theta_t + f(Q_t), Q_t, \varepsilon_t) + (1 - Q_t) P_P (a_0 + a_1 \log \theta_t + f(Q_t), Q_t, \varepsilon_t) \quad (41)
\]

*Proof.* See Appendix A.5

6.2 Dynamics: Steady-State Multiplicity and Hysteresis

We next characterize the steady states of optimism and their stability, for fixed aggregate fundamentals. This analysis highlights how associative, contagious optimism affects dynamics even in the absence of shocks.

**Steady-State Characterization.** Let \(T\) be the equilibrium transition map from Corollary 2 and \(T_{\theta}(Q) = T(Q, \theta, 0)\) be the map for a fixed value of aggregate productivity when there is no narrative shock. A level of optimism \(Q_\theta^*\) is a deterministic steady state for level of productivity \(\theta\) if it is a fixed point of the corresponding map, \(T_{\theta}(Q_\theta^*) = Q_\theta^*\). The following
result establishes that a deterministic steady state always exists and provides necessary and
sufficient conditions for extreme optimism and pessimism to be (stable) steady states.

**Proposition 2** (Steady State Existence, Multiplicity, and Stability). The following state-
ments are true:

1. There exists a deterministic steady-state level of optimism for every $\theta \in \Theta$
2. There exist thresholds $\theta_P$ and $\theta_O$ such that: $Q = 0$ is a deterministic steady state for
   $\theta$ if and only if $\theta \leq \theta_P$, and $Q = 1$ is a deterministic steady state for $\theta$ if and only if
   $\theta \geq \theta_O$. Moreover, these thresholds are given by:
   \[
   \theta_P = \exp \left\{ \frac{P_P^{-1}(0; 0) - a_0}{a_1} \right\} \quad \text{and} \quad \theta_O = \exp \left\{ \frac{P_O^{-1}(1; 1) - a_0 - f(1)}{a_1} \right\} \tag{42}
   \]
   where $P_P^{-1}(x; Q) = \sup\{Y : P_P(Y, Q, 0) = x\}$ and $P_O^{-1}(x; Q) = \inf\{Y : P_O(Y, Q, 0) = x\}$.

3. Extreme pessimism is stable if $\theta < \theta_P$ and $P_O(P_P^{-1}(0; 0), 0, 0) < 1$ and extreme optimism
   is stable if $\theta > \theta_O$ and $P_P(P_O^{-1}(1; 1), 1, 0) > 0$.

**Proof.** See Appendix A.6.

This result establishes conditions under which extreme optimism and pessimism can be
stable steady states. These conditions can be checked with only a few parameters: the
responsiveness of output to productivity $a_1$, its baseline level $a_0$, the impact of all agents
being optimistic on output $f(1)$, the highest level of output such that all pessimists remain
pessimistic when everyone is a pessimist $P_P^{-1}(0; 0)$, and the lowest level of output such that
all optimists remain optimistic when all other agents are optimists $P_O^{-1}(1; 1)$.

**Hysteresis.** Proposition 2 demonstrates the possibility for hysteresis: multiple steady
states of optimism that are entirely self-fulfilling. Thus, differing initial conditions of narra-
tives in the population can lead to differing steady-state levels of narrative penetration and
therefore output. The following corollary characterizes exactly when this can happen:

**Corollary 3** (Characterization of Extremal Multiplicity). Extreme optimism and pessimism
are simultaneously deterministic steady states for $\theta$ if and only if $\theta \in [\theta_O, \theta_P]$, which is non-
empty if and only if
\[
P_O^{-1}(1; 1) - P_P^{-1}(0; 0) \leq f(1) \tag{43}
\]

**Proof.** See Appendix A.7

---

28With the convention that the infimum of an empty set is $+\infty$ and the supremum of an empty set is $-\infty$.  

35
Figure 3: Illustration of Steady States and Dynamics Under the SSC Property

Notes: In each subfigure, the solid line is an example transition map \( T_\theta \), the dashed line is the 45-degree line, the dotted vertical line indicates the interior steady state \( \hat{Q}_\theta \), and the red arrows indicate the dynamics. The subfigures respectively correspond to SSC-A ("strict single crossing from above") and SSC-B ("strict single crossing from below"), as defined in the text.

To gain intuition for these results, and to derive a parametric condition for hysteresis that we will later empirically assess, we compute these conditions in our running LAC model:

Main Case (continuing from p. 30). In the LAC special case, we can compute the sufficient statistics for narrative updating analytically. In particular, we have that extreme optimism and pessimism can coexist if and only if:

\[
M = u + s + rf(1) - 1 \geq 0
\] (44)

which is to say that stubbornness, associativeness, contagiousness, and the equilibrium impact of optimism on output are sufficiently large. In Section 7.3, we will empirically assess this condition and its quantitative implications in our calibration.

△

To say more, we restrict attention to two important subclasses of updating rules that satisfy a natural single-crossing condition. We say that \( T \) is strictly single-crossing from above (SSC-A) if for all \( \theta \in \Theta \) there exists \( \hat{Q}_\theta \in [0, 1] \) such that \( T_\theta(Q) > Q \) for all \( Q \in (0, \hat{Q}_\theta) \) and \( T_\theta(Q) < Q \) for all \( Q \in (\hat{Q}_\theta, 1) \). We say that \( T \) is strictly single-crossing from below (SSC-B) if for all \( \theta \in \Theta \) there exists \( \hat{Q}_\theta \in [0, 1] \) such that \( T_\theta(Q) > Q \) for all \( Q \in (\hat{Q}_\theta, 1) \) and \( T_\theta(Q) < Q \) for all \( Q \in (0, \hat{Q}_\theta) \). If \( T \) is either SSC-A or SSC-B, we say that it is SSC. The left and right panels of Figure 3 illustrate examples of SSC-A and SSC-B transition maps as black solid lines.
Lemma 1 (Steady States under the SSC Property). If $T_\theta$ is SSC, then there exist at most three deterministic steady states. These correspond to extreme pessimism $Q = 0$, extreme optimism $Q = 1$, and intermediate optimism $Q = \hat{Q}_\theta$. Moreover, when $T_\theta$ is SSC-A: intermediate optimism is stable with a basin of attraction that includes $(0, 1)$; and whenever extreme optimism or extreme pessimism are steady states that do not coincide with $\hat{Q}_\theta$, they are unstable with respective basins of attraction $\{0\}$ and $\{1\}$. When $T_\theta$ is SSC-B: whenever extreme optimism is a steady state, it is stable with basin of attraction $(\hat{Q}_\theta, 1]$; whenever extreme pessimism is a steady state it is stable with basin of attraction $[0, \hat{Q}_\theta)$; and intermediate optimism is always unstable with basin of attraction $\{\hat{Q}_\theta\}$.

Proof. See Appendix A.8

In the SSC-A case there is a unique, (almost) globally stable steady state (left panel of Figure 3). In the SSC-B class, there exists a state-dependent criticality threshold $\hat{Q}_\theta \in [0, 1]$, below which the economy converges to extreme, self-fulfilling pessimism and above which the economy converges to extreme, self-fulfilling optimism (right panel of Figure 3). These two classes delineate two qualitatively different regimes for narrative dynamics: one with stable narrative convergence around a long-run steady state (SSC-A) and one with a strong role for initial conditions and hysteresis (SSC-B).

To understand the determinants of this criticality threshold, we study our LAC model:

Main Case (continuing from p. 30). The LAC model satisfies SSC-B if $u, r$, and $s$ are sufficiently large and $\theta \in (\theta_O, \theta_P)$. Moreover, in the SSC-B case, the criticality threshold is given by the unique solution to the equation:

$$\hat{Q}_\theta = \frac{u}{2}(2\hat{Q}_\theta - 1) + s\hat{Q}_\theta + r(a_0 + a_1 \log \theta + f(\hat{Q}_\theta)) \tag{45}$$

Thus, under the approximation that $f(Q) \approx kQ$, we have that:

$$\hat{Q}_\theta \approx \frac{\frac{u}{2} - r(a_0 + a_1 \log \theta)}{u + s + rk - 1} \tag{46}$$

Hence, greater contagiousness, associativeness, and decision relevance make the criticality threshold lower and therefore make it easier for an epidemic of extreme optimism to take hold.

6.3 Impulse Responses and Stochastic Fluctuations

Having characterized narrative dynamics with fixed fundamentals, we now study how the economy responds to deterministic and stochastic fundamental and narrative shocks. For
this analysis, we restrict attention to the SSC class, noting that this is an assumption solely on primitives.\textsuperscript{29}

**Hump-Shaped and Discontinuous Impulse Responses.** We consider the responses of aggregate output and optimism in the economy to a one-time positive shock to fundamentals from a steady state corresponding to $\theta = 1$:

$$
\theta_t = \begin{cases} 
1, & t = 0, \\
\hat{\theta}, & t = 1, \\
1, & t \geq 2.
\end{cases} \tag{47}
$$

where $\hat{\theta} > 1$. We would like to understand when the impulse response to a one-time shock is hump-shaped, meaning that there exists a $\hat{t} \geq 2$ such that $Y_t$ is increasing for $t \leq \hat{t}$ and decreasing thereafter. Moreover, we would like to understand how big a shock needs to be to send the economy from one steady state to another, as manifested as a discontinuity in the IRFs in the shock size $\theta$.

In the SSC-A case, IRFs are continuous in the shock but can nevertheless display hump-shaped dynamics as a result of the endogenous evolution of optimism.

**Proposition 3** (SSC-A Impulse Response Functions). In the SSC-A case, suppose that $Q_0 = \hat{Q}_1 \in (0, 1)$. The impulse response of the economy is given by:

$$
\begin{align*}
\log Y_t &= \begin{cases} 
a_0 + f(\hat{Q}_1), & t = 0, \\
a_0 + a_1 \log \hat{\theta} + f(\hat{Q}_1), & t = 1, \\
a_0 + f(Q_t), & t \geq 2
\end{cases}, \\
Q_t &= \begin{cases} 
\hat{Q}_1, & t \leq 1, \\
Q_2, & t = 2, \\
T_1(Q_{t-1}), & t \geq 3.
\end{cases}
\end{align*} \tag{48}
$$

Moreover, $Q_2 = \hat{Q}_1 P_\theta(a_0 + a_1 \log \hat{\theta} + f(\hat{Q}_1), \hat{Q}_1, 0) + (1 - \hat{Q}_1) P_P(a_0 + a_1 \log \hat{\theta} + f(\hat{Q}_1), \hat{Q}_1, 0) > \hat{Q}_1$, $Q_t$ is monotonically declining for all $t \geq 2$, and $Q_t \to \hat{Q}_1$. The IRF is hump-shaped if and only if $\hat{\theta} < \exp\{(f(Q_2) - f(\hat{Q}_1))/a_1\}$.

\textit{Proof.} See Appendix A.9

All persistence in the IRF of output derives from persistence in the IRF of optimism. There is a hump in the IRF for output if the boom induced by optimism exceeds the direct

\textsuperscript{29}This is without a substantive loss of generality as we can always represent any non-SSC $T_\theta$ as the concatenation of a set of restricted functions that are SSC on their respective domains. Concretely, whenever $T_\theta$ is not SSC, we can represent its domain $[0, 1]$ as a collection of intervals $\{I_j\}_{j \in J}$ such that $\bigcup_{j \in J} I_j = [0, 1]$ and the restricted functions $T_{\theta,j} : I_j \to [0, 1]$ defined by the property that $T_{\theta,j}(Q) = T_\theta(Q)$ for all $Q \in I_j$ are either SSC-A or SSC-B for all $j \in J$. Thus, applying our results to these restricted functions, we have a complete description of the global dynamics.
effect of the shock. This contrasts with the SSC-B case, wherein impulse responses can be discontinuous in the shock size. The following proposition characterizes the IRFs from the pessimistic steady state; those from the optimistic steady state are analogous.

**Proposition 4 (SSC-B Impulse Response Functions).** In the SSC-B case, suppose that $\theta_O < 1 < \theta_P$ and that $Q_0 = 0$. The impulse response of the economy is given by:

$$
\log Y_t = \begin{cases} 
a_0, & t = 0, 
a_0 + a_1 \log \hat{\theta}, & t = 1, 
a_0 + f(Q_t), & t \geq 2 
\end{cases} \quad Q_t = \begin{cases} 
0, & t \leq 1, 
P_P(\theta_0 + a_1 \log \hat{\theta}, 0, 0), & t = 2, 
T_1(Q_{t-1}), & t \geq 3. 
\end{cases}
$$

(49)

These impulse responses fall into the following four exhaustive cases:

1. $\hat{\theta} \leq \theta_P$, No Lift-Off: $Q_t = 0$ for all $t \in \mathbb{N}$.
2. $\hat{\theta} \in (\theta_P, \theta^*)$, Transitory Impact: $Q_t$ is monotonically declining for all $t \geq 2$ and $Q_t \to 0$.
3. $\hat{\theta} = \theta^*$, Permanent (Knife-edge) Impact: $Q_t = \hat{Q}_1$ for all $t \geq 1$
4. $\hat{\theta} > \theta^*$, Permanent Impact: $Q_t$ is monotonically increasing for all $t \geq 2$ and $Q_t \to 1$

where the critical shock threshold is $\theta^* = \exp\{ (P_P^{-1}(\hat{Q}_1; 0) - a_0)/a_1 \} > \theta_P$. In the transitory case, the output IRF is hump-shaped if and only if $\hat{\theta} < \exp\{ f(P_P(\theta_0 + a_1 \log \hat{\theta}, 0, 0))/a_1 \}$.

**Proof.** See Appendix A.10.

To understand this result, we first inspect the IRFs. At time $t = 0$, the economy lies at a steady state of extreme pessimism with $\log \theta_0 = 0$ and so $\log Y_0 = a_0$. At time $t = 1$, the one-time productivity shock takes place and output jumps up to $\log Y_1 = a_0 + a_1 \log \hat{\theta}$ as everyone remains pessimistic. At time $t = 2$, agents observe that output rose in the previous period. As a result, a fraction $P_P(\log Y_1, 0)$ of the population becomes optimistic. For output, the one-time productivity shock has dissipated, so output is now given by its unshocked baseline $a_0$ plus the equilibrium output effect of optimism $f(Q_2)$. From this point, the IRF evolves deterministically and its long-run behavior depends solely on whether the fraction that became initially optimistic exceeds the criticality threshold $\hat{Q}_1$ that delineates the basins of attraction of the steady states of extreme optimism and extreme pessimism.

As a result, productivity shocks have the potential for the following four qualitatively distinct effects, described in Proposition 4 and illustrated numerically in Figure 4. First, if a shock is small and no agent is moved toward optimism, the shock has a one-period impact on aggregate output. Second, if some agents are moved to optimism by the transitory boost to output but this fraction lies below the criticality threshold, then output steadily declines...
Figure 4: Illustration of IRFs in an SSC-B Case

Notes: The plots show the deterministic impulse responses of $Q_t$ and $\log Y_t$ in a model calibration with LAC updating. The four initial conditions correspond to the four cases of Proposition 4.

back to its pessimistic steady-state level as optimism was not sufficiently great to be self-fulfilling. Third, in the knife-edge case, optimism moves to a new (unstable) steady state and permanently increases output. Fourth, when enough agents are moved to optimism by the initial boost to output, then the economy converges to the fully optimistic steady state and optimism is completely self-fulfilling.

The impulse responses to narrative shocks are identical to those described above. One can take the formulas in Propositions 3 and 4 from $t \geq 2$ and set $Q_2$ equal to the value of $Q$ that obtains following the narrative shock $\varepsilon$. It follows that the qualitative nature of the impulse response to a narrative shock is identical to that of a fundamental shock.

Stochastic Boom-Bust Cycles. Having characterized the deterministic impulse propagation mechanisms at work in the economy, we now turn to understand the stochastic properties of the path of the economy as it is hit by fundamental and narrative shocks.

To this end, we analytically study the period of boom and bust cycles: the expected time that it takes for the economy to move from a state of extreme pessimism to a state of extreme optimism, and vice versa. Formally, define these expected stopping times as:

$$T_{PO} = \mathbb{E} \left[ \min\{\tau \in \mathbb{N} : Q_\tau = 1\} \mid Q_0 = 0 \right] ; T_{OP} = \mathbb{E} \left[ \min\{\tau \in \mathbb{N} : Q_\tau = 0\} \mid Q_0 = 1 \right]$$

where the expectation is taken under the true data generating process for the aggregate component of productivity $H$, which may or may not coincide with one of the narratives.
under consideration, and that of the narrative shocks $G$.

The following result provides sharp upper bounds, in the sense that they are attained for some $(H, G)$, on these stopping times as a function of deep structural parameters:

**Proposition 5** (Period of Boom-Bust Cycles). The expected regime-switching times satisfy the following inequalities:

\[
T_{PO} \leq \frac{1}{1 - \mathbb{E}_G \left[ H \left( \exp \left\{ \frac{P^\dagger_{P}(1,0;\varepsilon) - a_0}{a_1} \right\} \right) \right]}
\]

\[
T_{OP} \leq \frac{1}{\mathbb{E}_G \left[ H \left( \exp \left\{ \frac{P^\dagger_{O}(0;1,\varepsilon) - a_0 - f(1)}{a_1} \right\} \right) \right]}
\]

(51)

where $P^\dagger_{P}(x; Q, \varepsilon) = \inf\{Y : P_P(Y, Q, \varepsilon) = x\}$ and $P^\dagger_{O}(x; Q, \varepsilon) = \sup\{Y : P_O(Y, Q, \varepsilon) = x\}$. Moreover, when $P^\dagger_{O}(0; 1, 0) - P^\dagger_{P}(1; 0, 0) \leq f(1)$, these bounds are tight in the sense that they are attained for some processes for fundamentals and narrative shocks $(H, G)$.

**Proof.** See Appendix A.11

This result establishes that the economy regularly oscillates between times of booms and busts. We establish this result by postulating fictitious processes for optimism and showing that they bound, path-by-path, the true optimism process. This enables us to construct stopping times that dominate the true stopping times in the sense of first-order stochastic dominance and have expectations that can be computed analytically, thus providing the claimed bounds. We establish that these bounds are tight by constructing a family of distributions $(H, G)$ such that the fictitious processes coincide always with the true processes.\(^{30}\)

We can provide insights into the determinants of the period of boom-bust cycles from these analytical bounds. Concretely, consider the bound on the expected time to reach a bust from a boom. This bound is small when the quantity $\mathbb{E}_G \left[ H \left( \exp \left\{ \frac{P^\dagger_{P}(1,0;\varepsilon) - a_0}{a_1} \right\} \right) \right]$ is large, which happens when there is a fat left tail of fundamentals, when it is relatively easier for optimists to switch to pessimism as measured by $P^\dagger_{P}(0; 1, \varepsilon)$, and when co-ordination motives are weak as measured by $f(1)$.

### 6.4 Additional Results and Extensions

Before proceeding to our quantification of the model, we briefly summarize additional results and extensions contained within the Appendix.

\(^{30}\)We moreover show that elements of this family can be attained by taking the limit of normal mixtures with sufficiently dispersed means. Thus, for sufficiently dispersed $\mu_O$ and $\mu_P$, we can therefore construct $(H, G)$ for which the bound is attained by taking weighted averages of the optimistic and pessimistic narratives, making the uncertainty under each sufficiently small, and eliminating narrative shocks.
**Welfare Implications.** So far, we have studied the positive implications of fluctuations in optimism. In Appendix B.2, we study the normative implications of optimism and provide conditions under which its presence is welfare improving, despite it being misspecified. Intuitively, optimism acts as an *ad valorem* price subsidy for firms, which induces firms to hire more and can undo distortions caused by market power.

**Continuous Optimism.** Our baseline model featured, as in our main empirical specifications, only two narratives. In Appendix B.3, we generalize the setting studied in this section to feature a continuum of models. We show that very similar dynamics for both real output and narratives obtain in this specification of the model and the condition for extremal multiplicity is almost identical. Thus, the qualitative and quantitative features of the baseline model carry over to this richer setting.

**Multi-dimensional Narratives and Persistent Fundamentals.** In the conceptual framework and our measurement, we allowed for a general set of narratives. However, in our main theoretical analysis, we restricted attention to two different narratives where agents differ only in their optimism. In Appendix B.5, we extend the baseline model to allow for arbitrarily many narratives regarding the mean, persistence, and volatility of fundamentals, which is essentially exhaustive within the Gaussian class. We characterize quasi-linear equilibrium in this richer setting and show how qualitatively similar dynamics obtain.

**Persistent Idiosyncratic Shocks and Narrative Updating.** Empirically, we found that firms that experience positive idiosyncratic shocks are more likely to become optimistic. In Appendix B.6, we extend the multi-dimensional narrative equilibrium characterization when we allow for persistent idiosyncratic states and updating that depends on realized idiosyncratic states. When idiosyncratic shocks are fully transitory, this is of no consequence and our equilibrium characterization is identical. However, when idiosyncratic shocks are persistent, the fact that narrative updating depends on idiosyncratic shock realizations induces dependence between an agent’s narrative and their idiosyncratic productivity state. This matters for equilibrium output only insofar as it induces a time-varying covariance between and optimism and productivity. We find no empirical evidence for cyclicality of this covariance. We therefore abstract from this channel in our quantitative analysis.

**Contrarianism, Endogenous Cycles, and Chaos.** While this model generates narratively driven fluctuations, it cannot generate fully endogenous cycles and chaotic dynamics. In Appendix B.7, we extend this model to allow for contrarianism and the possibility that pessimists may be more likely to become optimists than optimists are to remain optimists. Allowing for these features generates the possibility of endogenous cycles of arbitrary period and topological chaos (sensitivity to arbitrarily small changes in initial conditions).
model also admits a structural test for the presence of cycles and chaos that we bring directly to the data and reject at the 95% confidence level that either cycles or chaos obtain.

**Narratives in Games and the Role of Higher-Order Beliefs.** We have studied narratively driven fluctuations in a business-cycle model, but our insights apply to co-ordination games much more generally. In Appendix B.8, we study contagious narratives in beauty contests Morris and Shin (2002), in which agents’ best replies are a linear function of their expectations of fundamentals and the average actions of others. Many models of aggregative games in macroeconomics and finance can be recast as such games when (log-)linearized (for a review, see Angeletos and Lian, 2016). We characterize equilibrium in this context and show how optimism percolates through the hierarchy of higher-order beliefs about fundamentals.

### 7 Quantifying the Impact of Narratives

We now combine our model and empirical results to gauge the quantitative effects of narratives on business cycles and their qualitative properties. First, combining our narrative optimism time series with our calibration of partial- and general-equilibrium effects of optimism, we find that optimism explains 32% of the reduction in GDP over the early 2000s recession, 18% over the Great Recession. Next, calibrating the dynamics of optimism to match our empirical results, we find that narrative optimism generates 19% of the variance in output. Finally, we study the macroeconomic consequences of all of the decision-relevant narratives together. We reject the condition for extremal multiplicity and hysteresis for optimism, but fail to reject it for other decision-relevant narratives. We then show in an extended model how multiple latent narratives may co-evolve and drive emergent optimism. Taken together, we therefore find that contagious narratives may explain a significant fraction of the US business cycle.

#### 7.1 Calibrating the Model

To obtain numerical predictions from the model, we need to know (i) the static relationship between output and optimism; (ii) the data-generating process for fundamental shocks; and (iii) the updating process for optimists and pessimists. We provide the model calibration in Table 6 and additional details in Appendix F.

First, we have shown in Section 6 that, to identify the static relationship between output and optimism, we need to estimate \( f \). In turn, \( f \) requires knowledge of: \( \delta^{OP} \), the partial-equilibrium effect of optimism on hiring; \( \alpha \), the returns-to-scale parameter; \( \epsilon \), the elasticity of substitution between varieties; and \( \omega \), the extent of complementarity (which itself depends

Notes: “Fixed” parameters are externally set. “Calibrated” parameters are chosen to hit various moments. Our specific calibration methods are described in Section 7.1.

on $\gamma$, indexing income effects in labor supply, and $\psi$, the inverse Frisch elasticity of labor supply). In our main analysis, we combine our baseline regression estimate of $\hat{\delta}^{OP} = 0.0355$ (see Table 1) with an external calibration of $\alpha, \epsilon, \gamma,$ and $\psi$, which together also pin down $\omega$. In Section 7.2, we study the sensitivity of our results to this external calibration, and we introduce two other calibration strategies for complementarity: using estimates of demand multipliers from the literature and inferring a demand multiplier for optimism using our own firm-level regressions.

For the external calibration, we impose that intermediate goods firms have constant returns-to-scale or $\alpha = 1$, which has been argued by Basu and Fernald (1997), Foster, Haltiwanger, and Syverson (2008), and Flynn, Traina, and Gandhi (2019) to be a reasonable assumption for large US firms. Second, as noted by Angeletos and La’O (2010), $\gamma$ indexes wealth effects in labor supply, which are empirically very small (Cesarini, Lindqvist, Notowidigdo, and Östling, 2017). Hence, we set $\gamma = 0$ for our benchmark calibration. Third, we calibrate the inverse Frisch elasticity of labor supply at $\psi = 0.4$, which is within the range of standard macroeconomic estimates (Peterman, 2016). Finally, we calibrate the elasticity of substitution to match estimated markups from De Loecker, Eeckhout, and Unger (2020) of 60%, which implies that $\epsilon = 2.6$. Hence, altogether, this calibration implies an aggregate degree of strategic complementarity of $\omega = 0.49$. Finally, we observe that the calibration of $\delta^{OP}$ puts only one restriction on the parameters $\kappa$ and $\mu_O - \mu_P$, respectively the signal-to-noise ratio and the impact of optimism on agents’ prior means.

Second, we calibrate the process for fundamentals. To allow for persistence in both
fundamentals as well as any unmodelled factors, we calibrate a case of the model with persistent fundamentals based on the analysis in Appendix B.5. Concretely, we suppose that \( \log \theta_t \) is a Gaussian AR(1) process with persistence \( \rho \) and IID innovations \( u_t \sim N(0, \sigma^2) \):

\[
\log \theta_t = \rho \log \theta_{t-1} + u_t
\]

(52)

To obtain the law of motion of aggregate output, we require three parameters \((\rho, \sigma, \kappa)\). We calibrate these to match the properties of fundamental output, defined as

\[
\log Y^f_t = \log Y_t - f(Q_t)
\]

(53)

In Appendix F, we show that \( \log Y^f_t \) follows an ARMA(1,1) with white noise process \( \zeta_t \). To calculate \( \log Y^f_t \) in the data, we take \( \log Y_t \) as band-pass filtered US real GDP (Baxter and King, 1999), \( Q_t \) as our measured time series of aggregate optimism (see Figure 1), and \( f \) as our calibrated function.\(^{31}\) We estimate by maximum-likelihood the ARMA(1,1) process for \( Y^f_t \) and then set \((\rho, \sigma, \kappa)\) to exactly match the three estimated ARMA parameters. Upon obtaining \( \kappa \), the restriction on \( \kappa \) and \( \mu_O - \mu_P \) imposed by \( \delta^{OP} \) yields the value of \( \mu_O - \mu_P \).

Third, we calibrate the process for updating probabilities. We use our regression estimates of the LAC form (see Equation 29) which corresponds to the linear probability model (see Table 4).\(^{32}\) This yields values of \( u = 0.208 \) for stubbornness, \( r = 0.804 \) for associativeness, and \( s = 0.290 \) for contagiousness. We finally calibrate a shock process for \( \varepsilon_t \), the aggregate shocks for proclivity toward optimism. In particular, we assume that \( \varepsilon_t \sim N(0, \sigma^2_\varepsilon) \). Conditional on the rest of the calibration, we set \( \sigma^2_\varepsilon \) to match the time-series variance of optimism.

### 7.2 How Does Optimism Shape the Business Cycle?

Using the calibrated model, we now study the effects of optimism on the business cycle via two complementary approaches: (i) gauging the historical effect of swings in business optimism on US GDP and (ii) exploring the full dynamic implications of contagious and associative optimism in simulations.

\(^{31}\)We apply the Baxter and King (1999) band-pass filter to post-war quarterly US real GDP data (Q1 1947 to Q1 2022). We use a lead-lag length of 12 quarters, a low period of 6 quarters, and a high period of 32 quarters. We then average these data to the annual level.

\(^{32}\)While the linear probability model does not necessarily yield probabilities between zero and one, our estimates of \( u, r \) and \( s \) imply updating probabilities that are always between zero and one so long as output does not deviate by more than 30% (holding fixed \( \varepsilon \)) or there is a five-standard-deviation optimism shock (holding fixed output at steady state).
Figure 5: The Effect of Optimism on Historical US GDP

Notes: The “Real GDP Cycle” is calculated from a Baxter and King (1999) band-pass filter capturing periods between 6 and 32 quarters. The “Contribution of Optimism” is the model-implied effect of optimism on log output. The 95% confidence interval incorporates uncertainty from the calibration of $\delta^{OP}$ using the delta method.

The Effects of Optimism on US GDP. In our empirical exercise, which leveraged cross-sectional data on US firms’ optimism, the general-equilibrium effect of optimism on total production was the unidentified “missing intercept.” Now, equipped with the model calibration of general-equilibrium forces, we can return to the question of how changes in optimism have historically affected the US business cycle. Concretely, we calculate the time series of $f(Q_t)$, where $f$ is the calibrated function mapping aggregate optimism to aggregate output, which depends on the partial-equilibrium effect of optimism on hiring, returns-to-scale, and the demand multiplier, and $Q_t$ observed annual time series for business optimism, originally reported in Figure 1. We take the observed time path of aggregate optimism as given, and therefore use the estimated dynamics of optimism only to determine the shocks that rationalize this observed path.

Figure 5 illustrates our findings by plotting the cyclical component of real GDP (dashed line) and the contribution of measured optimism toward output according to our model (solid line with grey 95% confidence interval). We observe that cyclical optimism explains a meaningful portion of fluctuations, particularly the booms of the mid-1990s and the mid-2000s and the busts of 2000-2002 and 2007-2009.

We next zoom in on the contribution of optimism toward macroeconomic crashes in 2000-02 and 2007-09. Over each of these two downturns, we calculate the percentage of output

Notes: The first column gives the change in detrended, annualized real GDP over the stated periods. The second column gives the component of this change attributed to the change in aggregate optimism by the model. The third column is the fraction of the real GDP change explained by optimism, defined in Equation 54. Standard errors for columns 2 and 3 incorporate uncertainty from estimating $\delta^{OP}$ and are calculated using the delta method.

The decline in the optimism component of GDP explains 31.65% of the output loss between 2000 and 2002, and 18.06% of the output loss between 2007 and 2009.

To more systematically gauge the model-implied causes of the historical business cycle, we plot the sequence of fundamental output and optimism shocks that our model requires to match the realized optimism and output time series in Figure A11. Our model accounts for the early 2000s recession with a large negative optimism shock—$\varepsilon_{2001} = -0.08$, or -1.8 standard deviations in our calibration—and a moderate-sized shock to fundamental output. For the Great Recession, our model implies a larger shock to fundamentals along with a smaller optimism shock —$\varepsilon_{2008} = -0.06$ or -1.4 standard deviations. The larger contribution of, and shock to, optimism at the outset of the early 2000s recession is consistent with a story that a break in confidence, associated with the “dot com” crash in the stock market, spurred a recession despite sound economic fundamentals. This is further consistent with independent textual evidence that “crash narratives” in financial news were especially rampant in this period (Goetzmann, Kim, and Shiller, 2022).

Contagious Narratives and Economic Fluctuations: Simulation Results. To more fully describe the role of narrative dynamics in shaping the business cycle, we turn to model simulations which incorporate the fully calibrated process for how optimism spreads.
Notes: The left panel plots the fraction of variance, one-year autocovariance, and two-year autocovariance explained by endogenous optimism in model simulations. The right panel plots the total non-fundamental autocovariance. Both quantities are defined in Equation 56. In each figure, we plot results under three model scenarios: the baseline model with optimism shocks and optimism dynamics (blue), a variant model with no shocks, or \( \sigma^2 = 0 \) (orange), and a variant model with shocks but no dynamics for narrative spread, or \( u = r = s = 0 \) (green).

To produce a summary statistic for the contribution of optimism toward the covariance structure of output, we observe that the covariance of output at lag \( \ell \geq 0 \) can be decomposed into four terms:

\[
\text{Cov}[\log Y_t, \log Y_{t-\ell}] = \text{Cov}[\log Y^f_t, \log Y^f_{t-\ell}] + \text{Cov}[f(Q_t), f(Q_{t-\ell})] + \text{Cov}[f(Q_t), Y_{t-\ell}] + \text{Cov}[f(Q_{t-\ell}), Y_t]
\]

The first term captures the volatility and persistence of exogenous fundamentals (i.e., the driving productivity shocks). The second term captures the volatility and persistence of the non-fundamental component of output. The last two terms capture the relationship of optimism with past and future fundamentals, which arises from the co-evolution of narratives with economic outcomes.

We therefore define non-fundamental variance as the total autocovariance arising from endogenous optimism as the sum of the last three terms, as well as its fraction of total variance.
variance, at each lag $\ell$:

$$\text{Non-Fundamental Autocovariance}_\ell = \text{Cov}[\log Y_t, \log Y_{t-\ell}] - \text{Cov}[\log Y^f_t, \log Y^f_{t-\ell}]$$

$$\text{Share of Variance Explained}_\ell = \frac{\text{Non-Fundamental Autocovariance}_\ell}{\text{Cov}[\log Y_t, \log Y_{t-\ell}]}$$

We calculate these statistics at horizons $\ell \in \{0, 1, 2\}$ and under three model variants: the baseline model with shocks, a variant model which turns off the shocks (or sets $\sigma^2 = 0$), and a variant model that keeps the shocks but turns off the endogenous evolution of narratives (by setting $u = r = s = 0$).

We report our findings in Figure 6. Optimism explains 19% of contemporary variance ($\ell = 0$), and this fraction increases with the lag. At one-year and two-year lags, optimism explains 34% and 81% of output autocovariance, respectively. Thus, most medium-frequency (two-year) dynamics are produced by contagious optimism instead of fundamentals. The model without endogenous dynamics of optimism explains only 4% of output variance and, as optimism shocks are IID, 0% of output auto-covariance. Moreover, while the model without optimism shocks matches only 5% of output variance, it accounts for 17% and 61% of one-year and two-year output autocovariance. Interestingly, the separate contributions to output variance of shocks and endogenous dynamics sum to less than one half of their joint explanatory power. This result establishes that the contagiousness and associativeness of narratives are amplifying propagation mechanisms for exogenous sentiment shocks.

**Parametric Sensitivity Analysis.** In Table A19, we report sensitivity analysis of the conclusions above to different calibrations for the macroeconomic parameters. We first focus on the calibration of macroeconomic complementarity and, by extension, the demand multiplier. Recall that $f(Q) \approx \frac{\alpha \delta_{OP}}{1-\omega} Q$, where $\frac{1}{1-\omega}$ is the general equilibrium demand multiplier in our economy, $\alpha$ indexes the returns-to-scale, and $\delta_{OP}$ is the partial equilibrium effect of optimism on hiring. Our baseline calibration implies a multiplier of $\frac{1}{1-\omega} = 1.96$. In rows 1, 2, 3, and 4 we vary the multiplier by: (i) adjusting the inverse-Frisch elasticity 2.5 to match micro estimates (Peterman, 2016), (ii) allowing for greater income effects in labor supply $\gamma = 1$, (iii) matching the empirical estimates of the demand multiplier of 1.33 from Flynn, Patterson, and Sturm (2021), and (iv) estimating the general equilibrium multiplier by optimism semi-structurally by using the extent of omitted variables bias from omitting a time fixed effect in the regression of hiring on optimism (see Appendix F.3 for the details). Our numerical results from adjusting the multiplier, holding fixed ($\delta_{OP}, \alpha, \epsilon$), convey that the contribution of optimism is increasing in this number. We finally consider sensitivity to the

\[^{33}\text{As discussed in Online Appendix F, we always add a constant to LAC updating so 0.5 is the interior steady-state when output is at its steady state. Thus, the “no dynamics” variant sets } Q_{t+1} = 0.5 + \epsilon_t.\]
calibrations of the elasticity of substitution $\epsilon$ (row 5 of Table A19) and the returns-to-scale $\alpha$ (row 6 of Table A19) holding fixed the multiplier (via adjustment in $\psi$). Changing $\epsilon$ has close to no effect on our results, due to the aforementioned near-linearity of $f$. Reducing $\alpha$, or assuming decreasing returns to scale, dampens the effect of optimism on output because it implies a smaller production effect of our estimated effect of optimism on hiring.

7.3 Can Contagious Optimism Generate Hysteresis?

We have shown that the dynamics of optimism generate quantitatively significant business cycles. However, we have not yet explored the implications of narratives for hysteresis and long-run movements in output. Our theoretical analysis delimited two qualitatively different regimes for macroeconomic dynamics with contagious optimism: one with stochastic fluctuations around a stable steady state, and one with hysteresis and (almost) global convergence to extreme steady states. In which regime do the estimated dynamics lie?

For the LAC case which we have taken to the data, the necessary and sufficient condition for extremal multiplicity is given by Equation 44. We compute the empirical analog of this condition as:

$$\hat{M} = \hat{u} + \hat{s} + \hat{r}f(1) - 1$$

(57)

If $\hat{M} > 0$, the calibrated model features hysteresis in the dynamics of optimism and output; if $\hat{M} < 0$, the model features oscillations around a stable steady state. We find $\hat{M} = -0.44 < 0$ with a standard error of 0.052, implying stable oscillations and ruling out hysteresis dynamics. This reflects the fact that decision-relevance, stubbornness, contagiousness, and associativeness are sufficiently small for narrative optimism.

While we find that the model of narrative optimism is consistent with stable fluctuations, this conclusion could be overturned with higher stubbornness or higher contagiousness. Both parameters were somewhat imprecisely estimated in our empirical analysis. Moreover, we might suspect that they vary over time. For example, the rise of the internet and the corresponding increase in the speed with which ideas can spread may have increased contagiousness.

Therefore, we explore more carefully the sensitivity of our conclusions regarding optimism’s role for the business cycle to the calibration of these parameters. In Figure 7, we plot our point estimate of contagiousness and stubbornness as a plus and its 95% confidence interval as a dotted ellipse. We also plot, as a dashed line, the condition for $M = 0$; to the left of this line, $M < 0$, and to the right of this line, $M > 0$. To gauge whether optimism is an “outlier” among narratives in being so far from this line, we compare its estimates to those corresponding to our other thirteen decision-relevant narratives (Table 3). The asso-
Figure 7: Variance Decomposition for Different Values of Stubbornness and Contagiousness

Notes: Calculations vary $u$ and $s$, holding fixed all other parameters at their calibrated values. The shading corresponds to the fraction of variance explained by optimism, or Share of Variance Explained $\theta$ defined in Equation 56. The plus is our calibrated value from Table 6, and the dotted line is the boundary of a 95% confidence set. The dots are calibrated values for other narratives from Figure A9. The dashed line is the condition of extremal multiplicity from Corollary 3 and Equation 44.

Associated point estimates of $(s,u)$ for the other narratives are green dots in Figure 7. Several of the thirteen plotted points are close to the condition for extremal multiplicity. Two are across the threshold. Thus, if optimism were to have the stubbornness and contagiousness of either of these two narratives, the joint dynamics of optimism and output would feature hysteresis.\footnote{The narratives across the line are Topic 3 (Value, Fair, Loss) and Topic 6 (Stock, Compensation, Tax).}

How does extremal multiplicity interact with our model’s predictions for non-fundamental volatility? To isolate the role of endogenous propagation, our theoretical discussion of extremal multiplicity considered paths of the economy with shocks to neither fundamentals nor narratives. In the quantitative model, the economy is constantly buffeted with shocks that move optimism away from its steady state(s). To measure how this shapes macroeconomic dynamics, we also shade in Figure 7 the fraction of variance explained by non-fundamental optimism. In our baseline calibration, indicated by the plus, this is 19%. This figure is stable near the confidence interval associated with our calibration, suggesting that statistical
uncertainty about narrative propagation does not overly influence our results.

Near the condition for extremal multiplicity, non-fundamental variance reaches essentially 100% of total variance. This is because even small shocks have the potential to “go viral,” and the force pulling the economy toward an interior steady state (i.e., balanced optimism and pessimism) is weak. If optimism were to have the propagation of some of our other observed narratives, which lie close to this line, it could induce such violent fluctuations.\textsuperscript{35}

Finally, far to the right of the extremal multiplicity condition, contagious optimism explains little output variance. This is because the economy quickly settles into an extreme steady state, fully optimistic or fully pessimistic, and moves quickly back to this steady-state in response to shocks. Figure A13 shows this quantitatively by plotting, against the same \((s,u)\) grid, the fraction of time that the optimistic fraction \(Q_t\) lies outside of \([0.25, 0.75]\)—this is 0% at the baseline calibration, and essentially 100% in the calibrations featuring extremal multiplicity. In this region, while sentiment does not greatly affect output dynamics, it does affect the static level of output—moreover, path dependence in the early history of our simulation determines whether output is permanently high (optimism goes viral) or permanently low (pessimism goes viral). Thus, even in a stochastic economy, \(M\) remains a highly predictive statistic for the nature of the dynamics of the economy.

7.4 Multi-Dimensional Narratives: Hysteresis, Confluence, and Constellations

Our quantitative analysis thus far has focused on the overall dynamics of optimism and pessimism and their macroeconomic effects. In this final subsection, we study how multiple, more granular narratives may evolve, interact, and shape macroeconomic dynamics. To do this, we calibrate versions of the quantitative model to match the estimated properties of Shiller’s Perennial Economic Narratives and our unsupervised Latent Dirichlet Allocation estimation. While this analysis is necessarily more speculative, due to the richness of possible interactions between these narratives and the number of parameters required to discipline these interactions, we highlight two overall findings: (i) the more granular narratives have a higher tendency toward hysteresis and unstable dynamics, and (ii) “constellations” of more granular narratives, with qualitatively different evolution, may underlie the overall dynamics of sentiment in the economy.

\textsuperscript{35}Due to the presence of shocks to optimism, this prediction is symmetric around the extremal multiplicity threshold; in the variant model which turns off optimism shocks, which is closer to what we studied in the theory, the extremal multiplicity condition sharply delineates the regime in which optimism fluctuations contribute to output variance from the regime in which there is complete hysteresis (Figure A12).
**Figure 8:** Evaluating Potential for Hysteresis for All Decision-Relevant Narratives

![Graph showing the evaluation of hysteresis for different narratives.](image)

**Notes:** For the binary construction of each narrative, we estimate the parameters of the updating rule (see Figure A9) and the partial-equilibrium effect on hiring via a variant of Equation 12 (see Figure A10). We then calculate $\hat{M}_k = \hat{u}_k + \hat{s}_k + \hat{r}_k \hat{f}_k(1) - 1$. We report our point estimates for each narrative along with 95% confidence intervals error bars, calculated using the delta method.

**Hysteresis.** We first perform tests for the possibility of hysteresis for the other decision-relevant narratives. To do this, we estimate $\hat{M}_k$ (Equation 57) using the estimated stubbornness, associativeness, contagiousness, and partial equilibrium effects on hiring of the other thirteen narratives indexed by $k$. In models in which each of these narratives existed in isolation, the condition $M_k > 0$ would be necessary and sufficient for extremal multiplicity. We plot our estimates along with 95% confidence intervals in Figure 8. We find that many of our narratives have values for $M$ that are close to zero, while one narrative’s 95% confidence interval for $M$ contains zero. Thus, while we can reject that optimism features hysteresis dynamics, we cannot do so for all of the narratives that we consider. Heuristically, this finding matches up with the corresponding time series (see Figures 1, A2, A3): while optimism appears to fluctuate in a stable fashion, other narratives have time series that appear to undergo regime shifts, with many notably happening around the Great Recession.

**Confluence and Constellations in an Enriched Model.** Shiller (2020) argues that *constellations* of many smaller and semantically related narratives may reinforce one another to create strong economic and social effects, and that the *confluence* of seemingly unrelated narratives may explain business-cycle fluctuations. In our empirical analysis, we found two
pieces of evidence suggesting that the thirteen more granular narratives discussed above behave like a constellation. First, we found that more specific narratives significantly predict movements in optimism. Second, we found that optimism about any specific narrative affects hiring no differently than optimism alone.

To understand how this constellation structure for optimism may affect our macroeconomic predictions, we calibrate a modified quantitative model in which the granular narratives drive emergent optimism. In this model, there is a latent space of $K$ narratives, in which agents either believe or do not believe: $\lambda_{it} = (\lambda_{1,it}, \ldots, \lambda_{K,it}) \in \{0, 1\}^K$. Based on a vector of constellation weights $\beta = (\beta^1, \ldots, \beta^K)$, the probability that an agent is optimistic is given by $\beta^t \lambda_{it}$. Thus, the aggregate level of emergent optimism is given by $Q_t = \beta^t Q_{k,t}$, where $Q_{k,t} = \int_{[0,1]} \lambda_{k,it} \, di$ is the fraction of agents that believe in narrative $k$. Each narrative $k$ evolves according to LAC updating probabilities with stubbornness $u^k$, associativeness $r^k$, and contagiousness $s^k$, with Gaussian narrative shocks that are IID across $k$ with common variance $\sigma^2_e$. The rest of the model is the same as the baseline. Thus, while dynamics are the same conditional on the process for optimism, the process for emergent optimism through the latent evolution of narratives may differ.\footnote{A caveat to our approach is that we do not allow for any complementarity or substitutability in how contagious each narrative is. However, this does not mean that each narrative spreads independently. As each narrative affects decisions and decisions affect output, associativeness links the dynamics of the full set of narratives. Moreover, even in the absence of associativeness, optimism that emerges from the combination of separate nonlinear processes for narrative evolution could feature different dynamics.}

To calibrate the new parameters, we proceed in three steps. First, we run a firm-level regression of optimism on the loadings for the other narratives to estimate the $\beta^k$. We normalize the sign of each narrative such that its corresponding $\beta^k$ is positive, for comparability. Second, we use our estimated stubbornness, associativeness, and contagiousness parameters for each decision-relevant narrative and specify an LAC updating process for each given these parameters (see Figure A9). Finally, we calibrate the variance of the narrative shocks to match the time series variance of optimism. We describe the full details of this calibration approach in Appendix F.2.

We find that optimism explains 17% of total output variance, comparable to our baseline finding of 19%. In this sense, the “reduced-form” model of the entire optimism constellation delivers similar macroeconomic predictions to the more granular model. This implies that the evolution of multiple narratives can be captured through reduced-form sentiment, conditional on correctly specifying the process by which this sentiment spreads.

However, this similarity belies significant heterogeneity in how the granular narratives spread, which is in turn related to each narrative’s tendency to “go viral.” To illustrate this, observe that the variance in emergent optimism can be decomposed into components...
arising from each narrative’s variance, \( \text{Var}[Q_{k,t}] \), as well as a remainder arising from their covariance, which is quantitatively negligible (it equals -0.016). We find that the \( \text{Var}[Q_{k,t}] \) are considerably different across narratives. In Figure A14, we report a scatterplot of the individual \( \text{Var}[Q_{k,t}] \) against the calculated \( \hat{M}^k \) statistics. Narratives with high \( \hat{M}^k \) have markedly higher variance contributions, reflecting their more mercurial dynamics, as predicted by the theory. Practically speaking, this means that a few narratives with a great proclivity toward dramatic swings may be significant drivers of emergent optimism. Thus, notwithstanding the fact that it is sufficient to study emergent sentiment if one wishes to understand macroeconomic dynamics, modeling more granular narratives is essential for understanding the process by which sentiment emerges.

### 8 Conclusion

This paper studies the macroeconomic implications of contagious, belief-altering narratives. We develop a conceptual framework in which narratives form building blocks of agents’ beliefs, affect agents’ decisions, and spread contagiously and associatively between agents. We measure proxies for narratives among US firms and find evidence that narratives are decision-relevant, contagious, and associative. We find that a contagious, associative, and decision-relevant *optimism narrative* reflects a non-fundamental shifter of beliefs, corresponding to over-optimism about economic conditions. We develop a business-cycle model that embeds these findings and find that narratives can generate non-fundamentally driven boom-bust cycles, hysteresis, and impulse responses that are hump-shaped over time and discontinuous in the sizes of shocks. When we calibrate the model to match the data, we find that the business-cycle implications of narratives are quantitatively significant: we estimate that measured declines in optimism account for approximately 32% of the peak-to-trough decline in output over the early 2000s recession and 18% over the Great Recession.

An important issue that our analysis leaves unexplored is what “makes a narrative a narrative”—that is, in the language of our model, what microfounds the set of narratives and their contagiousness? A richer study of these issues would be essential to study policy issues, including both the interaction of standard macroeconomic policies with narratives and the potential effects of directly “managing narratives” via communication. Moreover, probing these deeper origins of narratives could further enrich the study of narrative constellations beyond our suggestive analysis, to account for the full economic, semantic, and psychological interactions among narratives in a complex world.

Appendices

A Omitted Derivations and Proofs

A.1 Derivation of Equations 3 and 5

We first provide two assumptions under which Equation 3 holds as a linear approximation with a quadratic error bound. In what follows, we impose the technical requirements that \( \mathcal{X} \) is convex, compact subset of \( \mathbb{R} \), \( \mathcal{Y} \) is a convex, compact subset of \( \mathbb{R}^n \), \( \Theta \) is a convex, compact subset of \( \mathbb{R}^m \), and \( \Omega \) is a convex, compact subset of \( \mathbb{R}^r \). We first assume regularity conditions on payoffs to ensure the sufficiency of first-order conditions for optimality:

**Assumption 1.** The utility function \( u \) is strictly concave and twice continuously differentiable. The conjectured aggregate outcome function \( \hat{Y} \) is continuously differentiable.

We next assume that agents’ information about the random fundamentals is generated by location experiments that are conditionally independent of the fundamental, agents’ preference shifters, and the narratives held by agents. We moreover assume that all narratives are equally sensitive to information.

**Assumption 2.** The agents’ information sets are generated by location experiments, i.e., \( s_{it} = \theta_t + \nu_{it} \), where \( \nu_{it} \) is a zero-mean random variable that is independent of \( \theta_t, \omega_i, \) and \( \lambda_{it} \). Moreover, conditional on the signal, the conditional expectation of \( \theta_t \) under each narrative \( k \) is given by \( \mathbb{E}_k[\theta_t|s_{it}] = \kappa s_{it} + (1 - \kappa)\mathbb{E}_k[\theta_t] + O(||s_{it}||^2) \).

A sufficient condition for this assumption to hold with no approximation error is that all fundamentals and signals are Gaussian and the signal-to-noise ratio of the signal is constant across all narratives. Under these two assumptions, we can derive the form of the regression equation and that, modulo any misspecification error, the conditional expectation function is linear.

**Proposition 6.** Under Assumptions 1 and 2, we have that:

\[
x_{it} = \gamma_i + \chi_t + \sum_{k \in \mathcal{K}} \delta_k \lambda_{k,it} + \varepsilon_{it} + O(||(x_{it}, Y_t, \theta_t, Q_t, \omega_i, \nu_{it}, \lambda_{it})||^2)
\]

where \( \varepsilon_{it} \) is a zero mean random variable that is uncorrelated with \( \gamma_i, \chi_t \) and \( \lambda_{it} \). Thus, net of the misspecification error, the conditional expectation function is given by:

\[
\mathbb{E}[x_{it}|i, t, \lambda_{it}] = \gamma_i + \chi_t + \sum_{k \in \mathcal{K}} \delta_k \lambda_{k,it}
\]
Proof. By Assumption 1, from the agents’ problems (Equation 2), their best replies must solve the following first-order condition (where we suppress all individual and time subscripts):

$$\mathbb{E}_{\pi,\lambda} \left[ u_x(x, \hat{Y}(\theta), \theta, \omega) | s \right] = 0$$

(60)

We linearize this first-order condition in \((x, Y, \theta, \omega)\) around values \((\bar{x}, \bar{Y}, \bar{\theta}, \bar{\omega})\) which satisfy \(u_x(\bar{x}, \bar{Y}, \bar{\theta}, \bar{\omega}) = 0\). This gives

$$\mathbb{E}_{\pi,\lambda} \left[ u_{xx}(x - \bar{x}) + u'_{xY}(Y - \bar{Y}) + u'_{x\theta}(\theta - \bar{\theta}) + u'_{x\omega}(\omega - \bar{\omega}) | s \right] + R = 0$$

(61)

where \((u_{xx}, u_{xY}, u_{x\theta}, u_{x\omega})\) are constants equal to the corresponding derivatives evaluated at \((\bar{x}, \bar{Y}, \bar{\theta}, \bar{\omega})\), the remainder \(R\) is \(O(||(x, Y, \theta, \omega)\|)^2)\). We can rearrange the above, and use the fact that \(\omega\) is known to the agent, to write:

$$x = \bar{x} + \frac{1}{|u_{xx}|} u'_{x\omega}(\omega - \bar{\omega}) + \frac{1}{|u_{xx}|} \mathbb{E}_{\pi,\lambda} \left[ u'_{xY}(Y - \bar{Y}) + u'_{x\theta}(\theta - \bar{\theta}) | s \right] + \frac{1}{|u_{xx}|} R$$

(62)

Moreover, we know that \(\hat{Y} = \hat{Y}(Q, \theta)\). Thus, assuming that \(\hat{Y}\) is continuously differentiable, we may linearize \(Y = \hat{Y} + Y_Q'(Q - \bar{Q}) + Y_\theta'(\theta - \bar{\theta}) + \hat{R}\), where \(\bar{Y} = \hat{Y}(\bar{Q}, \bar{\theta})\) and \(\hat{R}\) is the error induced by the approximation of \(\hat{Y}\), which is \(O(||Y, \theta\|^2)\). Substituting this approximation into Equation 62 gives

$$x = \bar{x} + \frac{1}{|u_{xx}|} u'_{x\omega}(\omega - \bar{\omega}) + \frac{1}{|u_{xx}|} \mathbb{E}_{\pi,\lambda} \left[ u'_{xY}Y_Q'(Q - \bar{Q}) + Y_\theta'(\theta - \bar{\theta}) \right] + u'_{x\theta}(\theta - \bar{\theta}) | s \right] + \hat{R}$$

$$= \gamma + \bar{\chi} + \mathbb{E}_{\pi,\lambda} \left[ \bar{\theta} | s \right] + \hat{R}$$

(63)

where \(\gamma = \bar{x} + \frac{1}{|u_{xx}|} u'_{x\omega}(\omega - \bar{\omega}) - \frac{1}{|u_{xx}|} u'_{xY}Y_Q'Q + Y_\theta'\bar{\theta} - \frac{1}{|u_{xx}|} u'_{x\theta}\bar{\theta}, \bar{\chi} = \frac{1}{|u_{xx}|} u'_{xY}Y_Q'Q, \) and \(\bar{\theta} = \frac{1}{|u_{xx}|} u'_{x\theta}\). We next re-write the conditional expectation of \(\bar{\theta}\) as linear in two arguments, the signal \(s\) and prior mean \(\mathbb{E}_{\pi,\lambda}[\bar{\theta}]\). Using first the linearity of the expectation operator and the linearity of forming beliefs from narratives, and second Assumption 2 to re-write each narrative-specific conditional expectation in terms of the signal and the prior, we write

$$\mathbb{E}_{\pi,\lambda} \left[ \bar{\theta} | s \right] = \sum_{k \in K} \lambda_k \mathbb{E}_k[\bar{\theta} | s] = \kappa \bar{s} + (1 - \kappa) \mathbb{E}_{\pi,\lambda}[\bar{\theta}] + \hat{R}$$

(64)

where \(\mathbb{E}_{\pi,\lambda}[\bar{\theta}] = \sum_{k \in K} \lambda_k \mathbb{E}_k[\bar{\theta}]\) is the average prior mean across narratives, \(\hat{R}\) is the error induced by the approximation and is \(O(||(\theta, \nu, \lambda)||^2)\), and the transformed signal is \(\bar{s} = \)
\[
\frac{1}{|\text{u}_{x'}|} (u'_{xY} Y'_{\theta} + u'_{x'\theta}) s = \tilde{\theta} + \tilde{\nu}, \text{ with } \tilde{\nu} = \frac{1}{|\text{u}_{x'}|} (u'_{xY} Y'_{\theta} + u'_{x'\theta}) \nu \text{ independent of } \tilde{\theta} \text{ and of mean zero by Assumption 2.}
\]

Defining \( \chi = \tilde{\chi} + \kappa \tilde{\theta}, \varepsilon = \kappa \tilde{\nu} \) and \( \delta_k = (1 - \alpha) \mathbb{E}_k[\tilde{\theta}] \), we may write:

\[
x = \gamma + \chi + \sum_{k \in \mathcal{K}} \delta_k \lambda_k + \varepsilon + \bar{R}
\]

(65)

where \( \bar{R} = \tilde{R} + \tilde{R} = O(||(x, Y, \theta, Q, \omega, \nu, \lambda)||^2) \). Re-introducing subscripts, we have \( \omega_i, Q_t, \tilde{\theta}_t, \lambda_{k, it} \) and \( \varepsilon_{it} \). Thus, we have the claimed regression equation:

\[
x_{it} = \gamma_i + \chi_t + \sum_{k \in \mathcal{K}} \delta_k \lambda_{k,it} + \varepsilon_{it} + O(||(x_{it}, Y_t, \theta_t, Q_t, \omega_i, \nu_{it}, \lambda_{it})||^2) \]

(66)

As \( \varepsilon_{it} \) has zero mean and is uncorrelated with \( \gamma_i, \chi_t \) and \( \lambda_{it} \), the claimed formula for the conditional expectation function follows.

We now turn to the narrative updating rule. We impose the following assumption:

**Assumption 3.** The updating rule \( P \) is continuously differentiable.

We finally derive Equation 5 under this condition:

**Proposition 7.** Under Assumption 3, we have that:

\[
\mathbb{P}[\lambda_{it} = \lambda|\lambda_{i,t-1}, Y_{t-1}, Q_{t-1}] = \zeta_{\lambda} + u'_{\lambda} \lambda_{i,t-1} + r'_{\lambda} Y_{t-1} + s'_{\lambda} Q_{t-1} + O(||(\lambda_{i,t-1}, Y_{t-1}, Q_{t-1})||^2)
\]

(67)

**Proof.** By definition we have that \( \mathbb{P}[\lambda_{it} = \lambda|\lambda_{i,t-1}, Y_{t-1}, Q_{t-1}] = P_{\lambda}(\lambda_{i,t-1}, Y_{t-1}, Q_{t-1}) \). Linearizing this expression under Assumption 3, we immediately have:

\[
\mathbb{P}[\lambda_{it} = \lambda|\lambda_{i,t-1} = \lambda', Y_{t-1}, Q_{t-1}] = \zeta_{\lambda} + u_{\lambda,\lambda'} + r'_{\lambda} Y_{t-1} + s'_{\lambda} Q_{t-1} + O(||(\lambda_{i,t-1}, Y_{t-1}, Q_{t-1})||^2)
\]

(68)

Completing the proof.

**A.2 Proof of Proposition 1**

**Proof.** We guess and verify that there exists a unique quasi-linear equilibrium. That is, there exists a unique equilibrium of the following form for some parameters \( a_0, a_1 \in \mathbb{R} \) and function \( f : [0,1] \to \mathbb{R} \):

\[
\log Y(\theta, Q) = a_0 + a_1 \log \theta + f(Q)
\]

(69)

To verify this conjecture, we need to compute best replies under this conjecture and show that when we aggregate these best replies that the conjecture is consistent and, moreover, that it is consistent for a unique triple \( (a_0, a_1, f) \).
From the arguments in the main text, we need to compute two objects: \( \log E_{it} \left[ \theta_{it}^{1 + \psi \alpha / \alpha} \right] \) and \( \log E_{it} \left[ Y_{it}^{1 - \gamma} \right] \). We can compute the first object directly. Conditional on a signal \( s_{it} \) and a narrative weight \( \lambda_{it} \), we have that the distribution of the aggregate component of productivity is:

\[
\log \theta_{it} | s_{it}, \lambda_{it} \sim N \left( \kappa s_{it} + (1 - \kappa)(\lambda_{it} \mu_O + (1 - \lambda_{it}) \mu_P), \sigma^2_{\theta|s} \right)
\]  
(70)

by the standard formula for the conditional distribution of jointly normal random variables, where:

\[
\kappa = \frac{1}{1 + \sigma^2_{\theta}} \quad \text{and} \quad \sigma^2_{\theta|s} = \frac{1}{\sigma^2_{\theta} + \frac{1}{\sigma^2_{\theta}}}
\]  
(71)

with \( \kappa \) being the signal-to-noise ratio and \( \sigma^2_{\theta|s} \) the variance of fundamentals conditional on the signal. Thus, idiosyncratic productivity has conditional distribution given by:

\[
\log \theta_{it} | s_{it}, \lambda_{it} \sim N \left( \log \gamma_i + \kappa s_{it} + (1 - \kappa)(\lambda_{it} \mu_O + (1 - \lambda_{it}) \mu_P), \sigma^2_{\theta|s} + \sigma^2_{\tilde{\theta}} \right)
\]  
(72)

where we will denote the above mean by \( \mu_{it} \) and variance by \( \eta^2 \). Hence, rewriting and using the moment generating function of a normal random variable, we have that:

\[
\log E_{it} \left[ \exp \left\{ \frac{1}{\alpha} \log \theta_{it} \right\} \right] = -1 + \frac{\psi}{\alpha} \frac{\mu_{it}}{\mu_{it}} + \frac{1}{2} \left( \frac{1 + \psi}{\alpha} \right)^2 \eta^2
\]  
(73)

Under our conjecture (Equation 69), we can moreover compute:

\[
\log E_{it} \left[ Y_{it}^{1 - \gamma} \right] = \log E_{it} \left[ \exp \left\{ \left( \frac{1}{\epsilon} - \gamma \right) \left( a_0 + a_1 \log \theta_{it} + f(Q_t) \right) \right\} \right]
\]

\[
= \left( \frac{1}{\epsilon} - \gamma \right) \left[ a_0 + a_1 (\mu_{it} - \log \gamma_i) + f(Q_t) \right] + \frac{1}{2} a_1^2 \left( \frac{1}{\epsilon} - \gamma \right)^2 \left[ \eta^2 - \sigma^2_{\tilde{\theta}} \right]
\]  
(74)

Thus, we have that best replies under our conjecture are given by:

\[
\log x_{it} = \frac{1}{1 + \psi \alpha / \alpha} + \frac{1}{\epsilon} \log \left( \frac{1 - \frac{1}{\epsilon}}{1 + \psi \alpha / \alpha} \right) + \frac{1 + \psi}{\alpha} \mu_{it} - \frac{1}{2} \left( \frac{1 + \psi}{\alpha} \right)^2 \eta^2 \]

\[
+ \left( \frac{1}{\epsilon} - \gamma \right) \left[ a_0 + a_1 (\mu_{it} - \log \gamma_i) + f(Q_t) \right] + \frac{1}{2} a_1^2 \left( \frac{1}{\epsilon} - \gamma \right)^2 \left[ \eta^2 - \sigma^2_{\tilde{\theta}} \right]
\]  
(75)
To confirm the conjecture, we must now aggregate these levels of production and show that they are consistent with the conjecture. Performing this aggregation we have that:

\[
\log Y_t = \log \left[ \left\{ \int_{[0,1]} x_{it} \right\}^{\frac{1-\epsilon}{1-\epsilon^2}} \right]
\]

\[
= \frac{\epsilon}{\epsilon - 1} \log \mathbb{E}_t \left[ \exp \left\{ \frac{\epsilon - 1}{\epsilon} \log x_{it} \right\} \right]
\]

(76)

\[
= \frac{\epsilon}{\epsilon - 1} \log \mathbb{E}_t \left[ \mathbb{E}_t \left[ \exp \left\{ \frac{\epsilon - 1}{\epsilon} \log x_{it} \right\} | \lambda_{it} \right] \right]
\]

Moreover, expanding the terms in Equation 75, we have that:

\[
\log x_{it} = \frac{1}{1 + \psi - \alpha} + \frac{1}{\epsilon} \left[ \log \left( \frac{1 - \frac{1}{\epsilon}}{1 + \psi} \right) \right]
\]

\[
+ \frac{1 + \psi}{\alpha} \left[ \log \gamma_i + \kappa s_{it} + (1 - \kappa) \left[ \lambda_{it} \mu_O + (1 - \lambda_{it}) \mu_P \right] \right]
\]

\[- \frac{1}{2} \left( \frac{1 + \psi}{\alpha} \right)^2 \left( \sigma_{\theta|s}^2 + \sigma_\theta^2 \right)
\]

\[
+ \left( \frac{1}{\epsilon} - \gamma \right) \left[ a_0 + a_1 \left( \kappa s_{it} + (1 - \kappa) \left[ \lambda_{it} \mu_O + (1 - \lambda_{it}) \mu_P \right] \right) + f(Q_t) \right]
\]

\[
+ \frac{1}{2} a_1^2 \left( \frac{1}{\epsilon} - \gamma \right)^2 \left( \sigma_{\theta|s}^2 \right)
\]

(77)

which is, conditional on \( \lambda_{it} \), normally distributed as both \( \log \gamma_i \) and \( s_{it} \) are both normal. Hence, we write \( \log x_{it} | \lambda_{it} \sim N(\delta_t(\lambda_{it}), \hat{\sigma}^2) \), where:

\[
\delta_t(\lambda_{it}) = \frac{1}{1 + \psi - \alpha} + \frac{1}{\epsilon} \left[ \log \left( \frac{1 - \frac{1}{\epsilon}}{1 + \psi} \right) \right]
\]

\[
+ \frac{1 + \psi}{\alpha} \left[ \mu_\gamma + \kappa \log \theta_t + (1 - \kappa) \left[ \lambda_{it} \mu_O + (1 - \lambda_{it}) \mu_P \right] \right]
\]

\[- \frac{1}{2} \left( \frac{1 + \psi}{\alpha} \right)^2 \left( \sigma_{\theta|s}^2 + \sigma_\theta^2 \right)
\]

\[
+ \left( \frac{1}{\epsilon} - \gamma \right) \left[ a_0 + a_1 \left( \kappa \log \theta_t + (1 - \kappa) \left[ \lambda_{it} \mu_O + (1 - \lambda_{it}) \mu_P \right] \right) + f(Q_t) \right]
\]

\[
+ \frac{1}{2} a_1^2 \left( \frac{1}{\epsilon} - \gamma \right)^2 \left( \sigma_{\theta|s}^2 \right)
\]

(78)
and:

$$\sigma^2 = \left( \frac{1}{\frac{1+\psi}{\alpha} + \frac{1}{\epsilon}} \right)^2 \left[ \left( \frac{1+\psi}{\alpha} \right)^2 \sigma^2_\gamma + \kappa^2 \left[ \frac{1+\psi}{\alpha} + a_1 \left( \frac{1}{\epsilon} - \gamma \right) \right]^2 \sigma^2_\epsilon \right]$$  \hspace{1cm} (79)$$

Thus, we have that:

$$E_t \left[ \exp \left\{ \frac{\epsilon - 1}{\epsilon} \log x_{it} \right\} \mid \lambda_{it} \right] = \exp \left\{ \frac{\epsilon - 1}{\epsilon} \delta_t(\lambda_{it}) + \frac{1}{2} \left( \frac{\epsilon - 1}{\epsilon} \right)^2 \sigma^2 \right\}$$  \hspace{1cm} (80)$$

and so:

$$E_t \left[ E_t \left[ \exp \left\{ \frac{\epsilon - 1}{\epsilon} \log x_{it} \mid \lambda_{it} \right\} \right] \right] = Q_t \exp \left\{ \frac{\epsilon - 1}{\epsilon} \delta_t(1) + \frac{1}{2} \left( \frac{\epsilon - 1}{\epsilon} \right)^2 \sigma^2 \right\} + (1 - Q_t) \exp \left\{ \frac{\epsilon - 1}{\epsilon} \delta_t(0) + \frac{1}{2} \left( \frac{\epsilon - 1}{\epsilon} \right)^2 \sigma^2 \right\}$$  \hspace{1cm} (81)$$

Yielding:

$$\log Y_t = \delta_t(0) + \frac{1}{2} \frac{\epsilon - 1}{\epsilon} \sigma^2 + \frac{\epsilon}{\epsilon - 1} \log \left( Q_t \exp \left\{ \frac{\epsilon - 1}{\epsilon} (\delta_t(1) - \delta_t(0)) \right\} \right) + (1 - Q_t)$$  \hspace{1cm} (82)$$

where we define \( \alpha \delta_{OP} = \delta_t(1) - \delta_t(0) \) and compute:

$$\delta_t(1) - \delta_t(0) = \frac{1}{\frac{1+\psi-a}{\alpha} + \frac{1}{\epsilon}} \left( \frac{1+\psi}{\alpha} + a_1 \left( \frac{1}{\epsilon} - \gamma \right) \right) (1 - \kappa)(\mu_O - \mu_P) = \alpha \delta_{OP}$$  \hspace{1cm} (83)$$

and note that this is a constant. Finally, we see that \( \delta_t(0) \) is given by:

$$\delta_t(0) = \frac{1}{\frac{1+\psi-a}{\alpha} + \frac{1}{\epsilon}} \left[ \log \left( \frac{1 - \frac{1}{\epsilon}}{\frac{1+\psi}{\alpha}} \right) + \frac{1+\psi}{\alpha} (\mu_\gamma + (1 - \kappa) \mu_P) - \frac{1}{2} \left( \frac{1+\psi}{\alpha} \right)^2 \left( \sigma^2_{\theta|s} + \sigma^2_\theta \right) \right] + \left( \frac{1}{\epsilon} - \gamma \right) (a_0 + a_1 (1 - \kappa) \mu_P) + \frac{1}{2} a_1^2 \left( \frac{1}{\epsilon} - \gamma \right)^2 \sigma^2_{\delta|s}$$

$$+ \left[ \frac{1+\psi}{\alpha} + a_1 \left( \frac{1}{\epsilon} - \gamma \right) \right] \kappa \log \theta_t + \left( \frac{1}{\epsilon} - \gamma \right) f(Q_t)$$  \hspace{1cm} (84)$$

By matching coefficients between Equations 82 and Equation 69, we obtain \( a_0, a_1, \) and \( f. \)
We first match coefficients on \( \log \theta_t \) to obtain an equation for \( a_1 \):

\[
a_1 = \left[ \frac{1 + \psi}{\alpha} + a_1 \left( \frac{1}{\epsilon} - \gamma \right) \right] \kappa \quad (85)
\]

Under our maintained assumption that \( \frac{1 - \gamma}{1 + \psi - \alpha + \frac{1}{\epsilon}} \in [0, 1) \), as \( \kappa \in [0, 1] \), we have that this has a unique solution:

\[
a_1 = \frac{\frac{1 + \psi}{\alpha} \kappa}{1 - \left( \frac{1}{\epsilon} - \gamma \right) \kappa} \quad (86)
\]

It is moreover positive.

Second, by collecting terms with \( Q_t \) we obtain an equation for \( f \):

\[
f(Q) = \frac{\frac{1}{\epsilon} - \gamma}{1 + \psi - \alpha + \frac{1}{\epsilon}} f(Q) + \frac{\epsilon}{\epsilon - 1} \log \left( 1 + Q \left[ \exp \left\{ \frac{\epsilon - 1}{\epsilon} \alpha \delta^{OP} \right\} - 1 \right] \right) \quad (87)
\]

which has a unique solution as \( \frac{1 - \gamma}{1 + \psi - \alpha + \frac{1}{\epsilon}} \in [0, 1) \) and can be solved to yield:

\[
f(Q) = \frac{\frac{\epsilon}{(1 - \gamma) \kappa}}{1 - \left( \frac{1}{\epsilon} - \gamma \right) \kappa} \log \left( 1 + Q \left[ \exp \left\{ \frac{\epsilon - 1}{\epsilon} \alpha \delta^{OP} \right\} - 1 \right] \right) \quad (88)
\]

where we observe that \( \delta^{OP} \) depends only on primitive parameters and \( a_1 \), for which we have already solved. Finally, by collecting constants, we obtain an equation for \( a_0 \):

\[
a_0 = \frac{1}{1 + \psi - \alpha + \frac{1}{\epsilon}} \left[ \log \left( \frac{1 - \frac{1}{\epsilon}}{1 + \psi - \alpha} \right) + \frac{1 + \psi}{\alpha} (\mu_\gamma + (1 - \kappa) \mu_P) - \frac{1}{2} \left( \frac{1 + \psi}{\alpha} \right)^2 (\sigma_{\theta|s}^2 + \sigma_{\hat{\theta}}^2) 
+ \left( \frac{1}{\epsilon} - \gamma \right) a_1 (1 - \kappa) \mu_P \right] + \frac{1}{2} a_1^2 \left( \frac{1}{\epsilon} - \gamma \right)^2 \sigma_{\theta|s}^2 \right] + \frac{\epsilon}{2} - \frac{1}{\epsilon} \hat{\sigma}^2 \quad (89)
\]

Solving this equation yields:

\[
a_0 = \frac{1}{1 - \left( \frac{1}{\epsilon} - \gamma \right) a_1 (1 - \kappa) \mu_P} \left[ \log \left( \frac{1 - \frac{1}{\epsilon}}{1 + \psi - \alpha} \right) + \frac{1 + \psi}{\alpha} (\mu_\gamma + (1 - \kappa) \mu_P) - \frac{1}{2} \left( \frac{1 + \psi}{\alpha} \right)^2 (\sigma_{\theta|s}^2 + \sigma_{\hat{\theta}}^2) 
+ \left( \frac{1}{\epsilon} - \gamma \right) a_1 (1 - \kappa) \mu_P + \frac{1}{2} a_1^2 \left( \frac{1}{\epsilon} - \gamma \right)^2 \sigma_{\theta|s}^2 \right] + \frac{\epsilon}{2} - \frac{1}{\epsilon} \hat{\sigma}^2 \quad (90)
\]
which we observe depends only on parameters, \( a_1 \), and \( \hat{\sigma}^2 \). Moreover, \( \hat{\sigma}^2 \) depends only on parameters and \( a_1 \). Thus, given that we have solved for \( a_1 \), we have now recovered \( a_0 \), \( a_1 \), and \( f \) uniquely and verified that there exists a unique quasi-linear equilibrium. Finally, to obtain the formula for the best reply of agents, simply substitute \( a_0 \), \( a_1 \), and \( f \) into Equation 77 and label the coefficients as in the claim.

\[ \text{A.3 Proof of the Claims in Remark 1} \]

We now prove the claims made in Remark 1. We have already shown that there exists a unique quasi-linear equilibrium. More generally, we seek to rule out an equilibrium of any other form. To do so, we show that there is a unique equilibrium when fundamentals are bounded by some \( M \in \mathbb{R}, \log \theta_t \in [-M,M], \log \gamma_i \in [-M,M], \log \tilde{\theta}_{it} \in [-M,M], \) and \( e_{it} \in [-M,M] \).

**Lemma 2.** When fundamentals are bounded, there exists a unique equilibrium

**Proof.** To this end, we can recast any equilibrium function \( \log Y(\theta,q) \) as one that solves the fixed point in Equation 37. In the case where fundamentals are bounded, this can be accomplished by demonstrating that the implied fixed-point operator is a contraction by verifying Blackwell’s sufficient conditions. More formally, consider the space of bounded, real-valued functions \( \mathcal{C} \) under the \( L^\infty \)-norm and consider the operator \( V_M : \mathcal{C} \to \mathcal{C} \) given by:

\[
V_M(g)(\theta,Q) = \frac{\epsilon}{\epsilon - 1} \log \mathbb{E}(\theta,Q) \left[ \exp \left\{ \frac{\epsilon - 1}{\epsilon + \psi - \alpha} \log \left( \frac{1 - \frac{1}{\epsilon}}{\alpha} \right) \right\} - \log \mathbb{E}(s,Q) \left[ \exp \left\{ - \frac{1 + \psi}{\alpha} \log \theta_{it} \right\} \right] + \log \mathbb{E}(s,Q) \left[ \exp \left\{ \left( \frac{1}{\epsilon} - \gamma \right) g \right\} \right] \right]
\]

(91)

The following two conditions are sufficient for this operator to be a contraction: (i) monotonicity: for all \( g, h \in \mathcal{C} \) such that \( g \geq h \), we have that \( V_M(g) \geq V_M(h) \) (ii) discounting: there exists a parameter \( c \in [0,1) \) such that for all \( g \in \mathcal{C} \) and \( a \in \mathbb{R}_+ \) and \( V_M(g + a) \leq V_M(g) + ca \).

Thus, as the space of bounded functions under the \( L^\infty \)-norm is a complete metric space, if Blackwell’s conditions hold, then by the Banach fixed-point theorem, there exists a unique fixed point of the operator \( V_M \).

To complete this argument, we now verify (i) and (ii). To show monotonicity, observe that \( \frac{1}{\epsilon} - \gamma \geq 0 \) as \( \omega \geq 0 \) and recall that \( \epsilon > 1 \). Thus, we have that:

\[
\log \mathbb{E}(s,Q) \left[ \exp \left\{ \left( \frac{1}{\epsilon} - \gamma \right) g \right\} \right] \geq \log \mathbb{E}(s,Q) \left[ \exp \left\{ \left( \frac{1}{\epsilon} - \gamma \right) h \right\} \right]
\]

(92)
for all \((s, Q)\). And so \(V_M(g)(\theta, Q) \geq V_M(h)(\theta, Q)\) for all \((\theta, Q)\). To show discounting, observe that:

\[
\log \mathbb{E}_{s,Q} \left[ \exp \left\{ \left( \frac{1}{\epsilon} - \gamma \right) (g + a) \right\} \right] = \log \mathbb{E}_{s,Q} \left[ \exp \left\{ \left( \frac{1}{\epsilon} - \gamma \right) g \right\} \right] + \left( \frac{1}{\epsilon} - \gamma \right) a \tag{93}
\]

And so:

\[
V_M(g + a)(\theta, Q) = \frac{1}{\epsilon - 1} \log \mathbb{E}_{s,Q} \left[ \exp \left\{ \frac{-1}{\epsilon} + \frac{\psi}{\alpha} \log \theta_{it} \right\} \right] + \log \mathbb{E}_{s,Q} \left[ \exp \left\{ \left( \frac{1}{\epsilon} - \gamma \right) g \right\} \right] + \left( \frac{1}{\epsilon} - \gamma \right) a \tag{94}
\]

where \(\omega \in [0, 1)\) by assumption. Note that the modulus of contraction \(\omega\) is precisely the claimed strategic complementarity parameter in Equation 24. This verifies equilibrium uniqueness.

Away from the case with bounded fundamentals, the above strategy cannot be used to demonstrate uniqueness. Even though the fixed-point operator still satisfies Blackwell’s conditions, the relevant function space now becomes any \(L^p\)-space for \(p \in (1, \infty)\) and the sup-norm over such spaces can be infinite, making Blackwell’s conditions insufficient for \(V\) to be a contraction. In this case, we show that the unique quasi-linear equilibrium in the unbounded fundamentals case is an appropriately-defined \(\epsilon\)-equilibrium for any \(\epsilon > 0\). Let the unique quasi-linear equilibrium we have guessed and verified be \(\log Y^*\). We say that \(g\) is a \(\epsilon\)-equilibrium if

\[
\|g - V_M(g)\|_p < \epsilon \tag{95}
\]

where \(\| \cdot \|_p\) is the \(L^p\)-norm. In words, \(g\) is a \(\epsilon\)-equilibrium if its distance from being a fixed point is at most \(\epsilon\). The following Lemma establishes that \(Y^*\) is a \(\epsilon\)-equilibrium for bounded fundamentals for any \(\epsilon > 0\) for some bound \(M\):

**Lemma 3.** For every \(\epsilon > 0\), there exists an \(M \in \mathbb{N}\) such that \(\log Y^*\) is a \(\epsilon\)-equilibrium.

**Proof.** Now extend from \(C, V_M : L^p(\mathbb{R}) \to L^p(\mathbb{R})\) as in Equation 91. We observe that \(V_M\) is continuous in the limit in \(M\) in the sense that \(V_M(g) \to V(g)\) as \(M \to \infty\) for all \(g \in L^p(\mathbb{R})\). This observation follows from noting that both \(\log \mathbb{E}_{s,Q} \left[ \exp \left\{ \frac{-1}{1+\psi} \log \theta_{it} \right\} \right]\) and \(\log \mathbb{E}_{s,Q} \left[ \exp \left\{ \left( \frac{1}{\epsilon} - \gamma \right) g \right\} \right]\) are convergent pointwise for \(M \to \infty\) for all \((s, Q)\). In Proposition 1, we showed that \(V(\log Y^*) = \log Y^*\). Thus, we have that: \(V_M(\log Y^*) \to \)
\[ V(\log Y^*) = \log Y^*, \] which implies that:

\[
\lim_{M \to \infty} ||\log Y^* - V_M(\log Y^*)||_p = 0
\] (96)

which implies that for every \( \varepsilon > 0 \), there exists a \( M \in \mathbb{N} \) such that:

\[
||\log Y^* - V_M(\log Y^*)||_p < \varepsilon \quad \forall M \in \mathbb{N} : M > \bar{M}
\] (97)

Completing the proof.

### A.4 Proof of Corollary 1

**Proof.** From Equation 77, we may express:

\[
\log x_{it} = \text{cons} + b_3 f(Q_t) + \frac{1 + \psi}{\alpha} (\log \gamma_i + \kappa s_{it}) + \left( \frac{1}{\epsilon} - \gamma \right) \frac{1 + \psi \kappa}{\alpha + 1 - \frac{(1 - \gamma)\kappa}{1 + \psi - \alpha + 1}} \kappa s_{it}
\]

\[
\frac{1}{1 + \psi - \alpha + 1} \left[ \frac{1 + \psi}{\alpha} + \left( \frac{1}{\epsilon} - \gamma \right) \frac{1 + \psi \kappa}{\alpha + 1 - \frac{(1 - \gamma)\kappa}{1 + \psi - \alpha + 1}} \right] (1 - \kappa) (\mu_O - \mu_P) \lambda_{it}
\] (98)

We substitute this expression into \( \log L_{it} = \frac{1}{\alpha} (\log x_{it} - \log \theta_{it}) \) to write

\[
\log L_{it} = -\frac{1}{\alpha} \log \theta_{it} + \text{cons} + c_4 f(Q_t) + \text{cons}_i
\]

\[
+ \frac{1}{\alpha} \left[ \frac{1 + \psi}{\alpha} + \left( \frac{1}{\epsilon} - \gamma \right) \frac{1 + \psi \kappa}{\alpha + 1 - \frac{(1 - \gamma)\kappa}{1 + \psi - \alpha + 1}} \right] \kappa \log \theta_{t}
\]

\[
+ \frac{1}{\alpha} \frac{1}{1 + \psi - \alpha + 1} \left[ \frac{1 + \psi}{\alpha} + \left( \frac{1}{\epsilon} - \gamma \right) \frac{1 + \psi \kappa}{\alpha + 1 - \frac{(1 - \gamma)\kappa}{1 + \psi - \alpha + 1}} \right] (1 - \kappa) (\mu_O - \mu_P) \lambda_{it}
\]

\[ + \xi'_{it} \]

where \( \xi'_{it} \sim N(0, \sigma^2) \) and IID. Comparing the above with the definition of \( \alpha \delta^{OP} \) in Equation 83, we see that the coefficient on \( \lambda_{it} \) in the above expression is \( \delta^{OP} \). Subtracting lagged labor from both sides gives the claimed regression equation. We finally observe from Equation 88 that \( f(Q) \) depends on \( (\epsilon, \gamma, \psi, \alpha) \) and \( \delta^{OP} \). Hence, given \( (\epsilon, \gamma, \psi, \alpha) \), \( f \) is identified uniquely from the studied regression estimate. □
A.5 Proof of Corollary 2

Proof. This is immediate by substituting Equation 38 into Equation 28.

A.6 Proof of Proposition 2

Proof. We prove the three claims in sequence.

(1) The map \( T_\theta : [0, 1] \rightarrow [0, 1] \) is continuous for all \( \theta \in \Theta \) as \( f \), \( P_O \) and \( P_P \) are continuous functions. Moreover, it maps a convex and compact set to itself. Thus, by Brouwer’s fixed point theorem, there exists a \( Q_\star_\theta \) such that \( Q_\star_\theta = T_\theta(Q_\star_\theta) \) for all \( \theta \in \Theta \).

(2) To characterize the existence of extremal steady states, observe that \( Q = 1 \) is a steady state for \( \theta \) if and only if \( T_\theta(1) = P_O(a_0 + a_1 \log \theta + f(1), 1, 0) = 1 \) and \( Q = 0 \) is a steady state for \( \theta \) if and only if \( T_\theta(0) = P_P(a_0 + a_1 \log \theta, 0, 0) = 0 \). Thus, \( Q = 1 \) is a steady state if and only if \( P_O^{-1}(1; 1) \leq a_0 + a_1 \log \theta + f(1) \) and \( Q = 0 \) is a steady state if and only if \( P_P^{-1}(0; 0) \geq a_0 + a_1 \log \theta \). To obtain the result as stated, we re-arrange these inequalities in terms of \( \log \theta \) and exponentiate.

(3) To analyze the stability of the extremal steady states, observe that if \( T'_\theta(Q) < 1 \) at a steady state \( Q \), then \( Q \) is stable. When it exists (which it does almost everywhere), we have that:

\[
T'_\theta(Q) = P_O(a_0 + a_1 \log \theta + f(Q), Q, 0) - P_P(a_0 + a_1 \log \theta + f(Q), Q, 0)
+ Q \frac{d}{dQ} P_O(a_0 + a_1 \log \theta + f(Q), Q, 0) + (1 - Q) \frac{d}{dQ} P_P(a_0 + a_1 \log \theta + f(Q), Q, 0)
\]

Thus, for \( \theta < \theta_P \) and \( Q = 0 \):

\[
T'_\theta(0) = P_O(a_0 + a_1 \log \theta, 0, 0) - P_P(a_0 + a_1 \log \theta, 0, 0)
+ \frac{d}{dQ} P_P(a_0 + a_1 \log \theta + f(Q), Q, 0) \bigg|_{Q=0}
\]

\[
= P_O(a_0 + a_1 \log \theta, 0, 0)
\]

where the second equality follows by observing that all of \( P_P \), \( \frac{\partial P_P}{\partial \log Y} \), and \( \frac{\partial P_P}{\partial Q} \) are zero for \( \theta < \theta_P \). Thus, we have that \( T'_\theta(0) < 1 \) when \( P_O(a_0 + a_1 \log \theta, 0, 0) < 1 \). Moreover, for \( \theta < \theta_P \), we have that: \( P_O(a_0 + a_1 \log \theta, 0, 0) \leq P_O(a_0 + a_1 \log \theta_P, 0, 0) = P_O(P_P^{-1}(0; 0), 0, 0) \). Thus, a sufficient condition for \( T'_\theta(0) < 1 \) for \( \theta < \theta_P \) is that \( P_O(P_P^{-1}(0; 0), 0, 0) < 1 \).
For $\theta > \theta_O$ and $Q = 1$, we have that:

$$T'_\theta(1) = P_O(a_0 + a_1 \log \theta + f(1), 1, 0) - P_P(a_0 + a_1 \log \theta + f(1), 1, 0)$$

$$+ \frac{d}{dQ} P_O(a_0 + a_1 \log \theta + f(1), 1, 0) |_{Q=1}$$

$$= 1 - P_P(a_0 + a_1 \log \theta + f(1), 1, 0)$$

(102)

where the second equality follows again by observing that $P_O = 1$ and both $\frac{\partial P_O}{\partial \log Y}$ and $\frac{\partial P_Q}{\partial Q}$ are zero for $\theta > \theta_O$. Hence, we have that $T'_\theta(1) < 1$ when $P_P(a_0 + a_1 \log \theta + f(1), 1, 0) > 0$. For $\theta > \theta_O$ we have that $P_P(a_0 + a_1 \log \theta + f(1), 1, 0) \geq P_P(a_0 + a_1 \log \theta_O + f(1), 1) = P_P(P_O^{-1}(1, 1), 1, 0)$. Thus, a sufficient condition for $T'_\theta(1) < 1$ for $\theta > \theta_O$ is that $P_P(P_O^{-1}(1, 1), 1, 0) > 0$. 

\[\square\]

A.7 Proof of Corollary 3

Proof. By Proposition 2, the extremal steady states coexist if and only if $\theta \in [\theta_O, \theta_P]$, which is non-empty if and only if $\theta_O \leq \theta_P$ which is equivalent to $P_O^{-1}(1; 1) - P_P^{-1}(0; 0) \leq f(1)$. 

\[\square\]

A.8 Proof of Lemma 1

Proof. Fix $\theta \in \Theta$. We first study the SSC-A case. By SSC-A of $T$ we have that there exists $\hat{Q}_\theta \in [0, 1]$ such that $T_\theta(Q) > Q$ for all $Q \in (0, \hat{Q}_\theta)$ and $T_\theta(Q) < Q$ for all $Q \in (\hat{Q}_\theta, 1)$. As $T_\theta$ is continuous we have that $T_\theta(\hat{Q}_\theta) = \hat{Q}_\theta$. Consider now some $Q_0 \in (0, 1)$ such that $Q_0 \neq \hat{Q}_\theta$.

We have that $T_\theta(Q_0) > \hat{Q}_\theta$ if $Q_0 < \hat{Q}_\theta$ and $T_\theta(Q_0) < \hat{Q}_\theta$ if $Q_0 > \hat{Q}_\theta$. Hence, there exists at most one $Q^* \in (0, 1)$ such that $T_\theta(Q^*) = Q^*$. Thus, there exist at most three steady states $Q^* = 0$, $Q^* = \hat{Q}_\theta$, and $Q^* = 1$.

To find the basins of attraction of these steady states, fix $Q_0 \in (0, 1)$ and consider the sequence $\{T^n_\theta(Q_0)\}_{n \in \mathbb{N}}$. For a steady state $Q^*$, its basin of attraction is:

$$B_\theta(Q^*) = \left\{ Q_0 \in [0, 1] : \lim_{n \to \infty} T^n_\theta(Q_0) = Q^* \right\}$$

(103)

First, consider $Q_0 \in (0, \hat{Q}_\theta)$. We now show by induction that $T^n_\theta(Q_0) \geq T^{n-1}_\theta(Q_0)$ for all $n \in \mathbb{N}$. Consider $n = 1$. We have that $T_\theta(Q_0) > Q_0$ as $T$ is SSC-A and $Q_0 < \hat{Q}_\theta$. Suppose now that $T^n_\theta(Q_0) \geq T^{n-1}_\theta(Q_0)$. We have that:

$$T^{n+1}_\theta(Q_0) = T_\theta \circ T^n_\theta(Q_0) \geq T_\theta \circ T^{n-1}_\theta(Q_0) = T^n_\theta(Q_0)$$

(104)

by monotonicity of $T_\theta$, which proves the inductive hypothesis. Observe moreover that the sequence $\{T^n_\theta(Q_0)\}_{n \in \mathbb{N}}$ is bounded as $T^n_\theta(Q_0) \in [0, 1]$ for all $n \in \mathbb{N}$. Hence, by the monotone
convergence theorem, \( \lim_{n \to \infty} T^n_\theta(Q_0) \) exists. Toward a contradiction, suppose that \( Q_0^\infty = \lim_{n \to \infty} T^n_\theta(Q_0) > \hat{Q}_\theta \). By SSC-A of \( T \) we have that \( T_\theta(Q_0^\infty) > Q_0^\infty \), but this contradicts that \( Q_0^\infty = \lim_{n \to \infty} T^n_\theta(Q_0) \). Thus, we have that \( Q_0^\infty = \hat{Q}_\theta \). Hence, \( (0, \hat{Q}_\theta) \subseteq B_\theta(\hat{Q}_\theta) \). Second, consider \( Q_0 = \hat{Q}_\theta \). We have that \( T_\theta(\hat{Q}_\theta) = \hat{Q}_\theta \). Thus, \( Q_0^\infty = \hat{Q}_\theta \). Hence, \( \hat{Q}_\theta \in B_\theta(\hat{Q}_\theta) \). Third, consider \( Q_0 \in (\hat{Q}_\theta, 1) \). Following the arguments of the first part, we have that \( (\hat{Q}_\theta, 1) \subseteq B_\theta(\hat{Q}_\theta) \). Thus, \( (0, 1) \subseteq B_\theta(\hat{Q}_\theta) \). Moreover, if \( Q = 0 \) or \( Q = 1 \) are steady states, they can only have basins of attraction in \([0, 1] \backslash B_\theta(\hat{Q}_\theta)\), which implies that they are unstable and can only have basins of attraction \( \{0\} \) and \( \{1\} \).

The analysis of the SSC-B case follows similarly. By SSC-B of \( T \) we have that there exists \( \hat{Q}_\theta \in [0, 1] \) such that \( T_\theta(Q) > Q \) for all \( Q \in (\hat{Q}_\theta, 1) \) and \( T_\theta(Q) < Q \) for all \( Q \in (0, \hat{Q}_\theta) \). As \( T_\theta \) is continuous, we have that \( T_\theta(\hat{Q}_\theta) = \hat{Q}_\theta \). Consider now some \( Q_0 \in (0, 1) \) such that \( Q_0 \neq \hat{Q}_\theta \). Observe that \( T_\theta(Q_0) < \hat{Q}_\theta \) if \( Q_0 < \hat{Q}_\theta \) and \( T_\theta(Q_0) > \hat{Q}_\theta \) if \( Q_0 > \hat{Q}_\theta \). Hence, there exists at most one \( Q^* \in (0, 1) \) such that \( T_\theta(Q^*) = Q^* \). Thus, there exist at most three steady states \( Q^* = 0 \), \( Q^* = \hat{Q}_\theta \), and \( Q^* = 1 \).

To find the basins of attraction of these steady states, first consider \( Q_0 \in (0, \hat{Q}_\theta) \). We now show by induction that \( T^n_\theta(Q_0) \leq T^{n-1}_\theta(Q_0) \) for all \( n \in \mathbb{N} \). Consider \( n = 1 \). We have that \( T_\theta(Q_0) < Q_0 \) as \( T \) is SSC-B and \( Q_0 < \hat{Q}_\theta \). Suppose now that \( T^n_\theta(Q_0) \leq T^{n-1}_\theta(Q_0) \). We have that:

\[
T^{n+1}_\theta(Q_0) = T_\theta \circ T^n_\theta(Q_0) \leq T_\theta \circ T^{n-1}_\theta(Q_0) = T^n_\theta(Q_0)
\]

by monotonicity of \( T_\theta \), which proves the inductive hypothesis. Observe moreover that the sequence \( \{T^n_\theta(Q_0)\}_{n \in \mathbb{N}} \) is bounded as \( T^n_\theta(Q_0) \in [0, 1] \) for all \( n \in \mathbb{N} \). Hence, by the monotone convergence theorem, \( \lim_{n \to \infty} T^n_\theta(Q_0) \) exists. Finally, toward a contradiction, suppose that \( Q_0^\infty = \lim_{n \to \infty} T^n_\theta(Q_0) > 0 \). By SSC-B of \( T \) we have that \( T_\theta(Q_0^\infty) < Q_0^\infty \), but this contradicts that \( Q_0^\infty = \lim_{n \to \infty} T^n_\theta(Q_0) \). Thus, we have that \( Q_0^\infty = 0 \). Hence, \( (0, \hat{Q}_\theta) \subseteq B_\theta(0) \). Second, consider \( Q_0 = \hat{Q}_\theta \). We have that \( T_\theta(\hat{Q}_\theta) = \hat{Q}_\theta \). Thus, \( Q_0^\infty = \hat{Q}_\theta \). Hence \( \hat{Q}_\theta \in B_\theta(\hat{Q}_\theta) \). Third, consider \( Q_0 \in (\hat{Q}_\theta, 1) \). By the exact arguments of the first part, we have that \( (\hat{Q}_\theta, 1) \subseteq B_\theta(1) \). Observing \( B_\theta(0) \), \( B_\theta(\hat{Q}_\theta) \), and \( B_\theta(1) \) are disjoint completes the proof.

**A.9 Proof of Proposition 3**

**Proof.** By Proposition 1 and substituting the form of the shock process from Equation 47, we obtain the formula for the output IRF. For the fraction of optimists, we see that:

\[
Q_2 = \hat{Q}_1 P_O(a_0 + a_1 \log \hat{\theta} + f(\hat{Q}_1), \hat{Q}_1, 0) + (1 - \hat{Q}_1) P_P(a_0 + a_1 \log \hat{\theta} + f(\hat{Q}_1), \hat{Q}_1, 0) > \hat{Q}_1 P_O(a_0 + f(\hat{Q}_1), \hat{Q}_1, 0) + (1 - \hat{Q}_1) P_P(a_0 + f(\hat{Q}_1), \hat{Q}_1, 0) = \hat{Q}_1
\]

(106)
and \( Q_t = T_1(\log Y_{t-1}, Q_{t-1}) \) for \( t \geq 3 \) by iterating forward. That \( Q_t \) monotonically declines to \( \hat{Q}_1 \) follows from Lemma 1 as we are in the SSC-A case. The hump shape is obtained if \( \log Y_1 \leq \log Y_2 \). This corresponds to

\[
\log Y_1 = a_0 + a_1 \log \hat{\theta} + f(\hat{Q}_1) \leq a_0 + f(Q_2) = \log Y_2
\]

which rearranges to the desired expression. \( \square \)

A.10 Proof of Proposition 4

Proof. We first derive the IRF functions. The formula for the output IRF follows Proposition 3. For the IRF for the fraction of optimists, we simply observe that \( Q_0 = Q_1 = 0 \) and \( Q_2 = P_P(a_0 + a_1 \log \hat{\theta}, 0, 0) \), and that \( Q_t = T_1(Q_{t-1}) \) for \( t \geq 3 \) by iterating forward.

We now describe the properties of the IRFs as a function of the size of the initial shock \( \hat{\theta} \). First, observe that \( Q_2 = P_P(a_0 + a_1 \log \hat{\theta}, 0, 0) \). Thus, we have that \( Q_2 = 0 \) if and only if \( P_P^{-1}(0; 0) \geq a_0 + a_1 \log \hat{\theta} \) which holds if and only if \( \hat{\theta} \leq \theta_P \). For any \( \hat{\theta} > \theta_P \) it follows that \( Q_2 > 0 \). As we lie in the SSC class, by Lemma 1, we have that the steady states \( Q = 0, Q = 1, \) and \( Q = \hat{Q}_1 \) have basins of attraction given by \([0, \hat{Q}_1), (\hat{Q}_1, 1), \{\hat{Q}_1\} \). Thus, if \( Q_2 < \hat{Q}_1 \), we have monotone convergence of \( Q_t \) to 0. If \( Q_2 = \hat{Q}_1 \), then \( Q_t = \hat{Q}_1 \) for all \( t \in \mathbb{N} \). If \( Q_2 > \hat{Q}_1 \), we have monotone convergence of \( Q_t \) to 1. Moreover, the threshold for \( \hat{\theta} \) such that \( Q_2 = \hat{Q}^* \) is \( \exp \left\{ \frac{P_P^{-1}(\hat{Q}_1; 0) - a_0}{a_1} \right\} \).

Finally, to find the condition such that the IRF is hump-shaped, we observe that this occurs if and only if \( f(Q_2) > a_1 \log \hat{\theta} \) as \( Q_t \) is monotonically decreasing for \( t \geq 2 \), which is precisely the claimed condition. \( \square \)

A.11 Proof of Proposition 5

Proof. We prove this result by first constructing fictitious processes for optimism that bound above and below the true optimism process for all realizations of \( \{\theta_t\}_{t \in \mathbb{N}} \) before the stopping time. We can then use this to bound the stopping times’ distributions in the sense of first-order stochastic dominance and use this fact to bound the expectations.

First, consider the case where we seek to bound \( \tau_{PO} = \min\{t \in \mathbb{N} : Q_t = 1, Q_0 = 0\} \). In the model, we have that \( Q_{t+1} = T(Q_t, \nu_t) \). Fix a path of fundamentals and narrative shocks \( \{\nu_t\}_{t \in \mathbb{N}} = \{\theta_t, \varepsilon_t\}_{t \in \mathbb{N}} \) and define the fictitious \( \overline{Q} \) process as:

\[
\overline{Q}_{t+1} = \mathbb{I}[T(\overline{Q}_t, \nu_t) = 1]
\]

with \( \overline{Q}_0 = 0 \). We prove by induction that \( \overline{Q}_t \leq Q_t \) for all \( t \in \mathbb{N} \). Consider first the base case
that $t = 1$:
\[
Q_1 = \mathbb{I}[T(0, \nu_0) = 1] \leq T(0, \nu_0) = Q_1
\] (109)

Toward the inductive hypothesis, suppose that $Q_{t-1} \leq Q_{t-1}$. Then we have that:
\[
Q_t = \mathbb{I}[T(Q_{t-1}, \nu_{t-1}) = 1] \leq \mathbb{I}[T(Q_{t-1}, \nu_{t-1}) = 1] \leq T(Q_{t-1}, \nu_{t-1}) = Q_t
\] (110)

where the first inequality follows by the property that $T(\cdot, \nu)$ is a monotone increasing function.

As $Q_t \leq Q_t$ for all $t \in \mathbb{N}$, we have that:
\[
\tau_{PO} = \min\{t \in \mathbb{N} : Q_t = 1, Q_0 = 0\} \geq \min\{t \in \mathbb{N} : Q_t = 1, Q_0 = 0\} = \tau_{PO}
\] (111)

Else, we would have at $\tau_{PO}$ that $Q_{\tau_{PO}} < Q_{\tau_{PO}}$, which is a contradiction.

We now have a pathwise upper bound on $\tau_{PO}$. We now characterize the distribution of the bound. Observe that the possible sample paths for $\{Q_t\}_{t \in \mathbb{N}}$ until stopping are given by the set:
\[
G_{PO} = \{(0^{(n-1)}, 1) : n \geq 1\}
\] (112)

Moreover, conditional on $Q_{t-1} = 0$, the distribution of $Q_t$ is independent of $\{\nu_s\}_{s \leq t-1}$. Thus, the fictitious stopping time $\tau_{PO}$ has a geometric distribution with parameter given by $\mathbb{P}[Q_{t+1} = 1|Q_t = 0]$. This parameter is given by:
\[
\mathbb{P}[Q_{t+1} = 1|Q_t = 0] = \mathbb{P}[P_P(a_0 + a_1 \log \theta_t, 0, \varepsilon_t) = 1]
\]
\[
= \mathbb{P}\left[\theta_t \geq \exp\left(\frac{P^\dagger_P(1; 0, \varepsilon_t) - a_0}{a_1}\right)\right]
\]
\[
= 1 - \mathbb{E}_G\left[H\left(\exp\left(\frac{P^\dagger_P(1; 0, \varepsilon_t) - a_0}{a_1}\right)\right)\right]
\] (113)

Thus, we have established a stronger result and provided a distributional bound on the stopping time:
\[
\tau_{PO} \leq \tau_{PO} \sim \text{Geo}\left(1 - \mathbb{E}_G\left[H\left(\exp\left(\frac{P^\dagger_P(1; 0, \varepsilon_t) - a_0}{a_1}\right)\right)\right]\right)
\] (114)

An immediate corollary is that:
\[
\tau_{PO} = \mathbb{E}[\tau_{PO}] \leq \mathbb{E}[\tau_{PO}] = \frac{1}{1 - \mathbb{E}_G\left[H\left(\exp\left(\frac{P^\dagger_P(1; 0, \varepsilon_t) - a_0}{a_1}\right)\right)\right]}
\] (115)
We can apply appropriately adapted arguments for the other case, where we now define:

\[ Q_{t+1} = \mathbb{I}[T(Q_t, \nu_t) \neq 0] \] (116)

with \( Q_0 = 1 \). In this case, by an analogous induction have that \( Q_{t} \geq Q_{t} \) for all \( t \in \mathbb{N} \) for all sequences \( \{\nu_t\}_{t \in \mathbb{N}} \). And so, we have that if \( Q_t \) has reached 0 then so too has \( Q_t \). The possible sample paths in this case are:

\[ \mathcal{G}_{OP} = \{(1^{(n-1)}, 0) : n \geq 1\} \] (117)

So again the stopping time has a geometric distribution, this time with parameter:

\[
\mathbb{P}[Q_{t+1} = 0|Q_t = 1] = \mathbb{P}\left[ \theta_t \leq \exp\left\{ \frac{P_0^+(0;1,\varepsilon_t) - a_0 - f(1)}{a_1} \right\} \right] = \mathbb{E}_G \left[ H\left( \exp\left\{ \frac{P_0^+(0;1,\varepsilon) - a_0 - f(1)}{a_1} \right\} \right) \right]
\] (118)

And so we have:

\[ T_{OP} \leq \frac{1}{\mathbb{E}_G \left[ H\left( \exp\left\{ \frac{P_0^+(0;1,\varepsilon) - a_0 - f(1)}{a_1} \right\} \right) \right]} \] (119)

It remains to show that these bounds are tight. To do so, we derive a law \( H \) such that \( Q_t = Q_t = Q_t \) for all \( t \in \mathbb{N} \). Concretely, define the set:

\[ \Theta^* = \left( -\infty, \exp\left\{ \frac{P_0^+(0;1,0) - a_0 - f(1)}{a_1} \right\} \right] \cup \left[ \exp\left\{ \frac{P_0^+(0;1,0) - a_0}{a_1} \right\}, \infty \right) \] (120)

and suppose that \( \theta \) takes values only in this set, where the two sub-intervals are disjoint as \( P_0^+(0;1,0) - P_0^+(1;0,0) \leq f(1) \). Moreover, suppose that narrative shocks equal zero with probability one. In this case, starting from \( Q_t = 1 \), the only possible values for \( Q_{t+1} \) are zero and one. Moreover, starting from \( Q_t = 0 \), the only possible values for \( Q_{t+1} \) are zero and one. Thus, in either case, \( Q_t = Q_t = Q_t \) pathwise and \( T_{OP} = T_{OP}^* \) and \( T_{PO} = T_{PO}^* \). It is worth noting that such a distribution can be obtained by considering a limit of normal-mixture distributions. Concretely, suppose that \( H \) is derived as a mixture of two normal distributions \( N(\mu_A, \sigma^2) \) and \( N(\mu_B, \sigma^2) \) for \( \mu_A < \exp\left\{ \frac{P_0^+(0;1,0) - a_0 - f(1)}{a_1} \right\} \) and \( \mu_B > \exp\left\{ \frac{P_0^+(1;0,0) - a_0}{a_1} \right\} \). Taking the limit as \( \sigma \to 0 \), the support of \( H \) converges to being contained within \( \Theta^* \).

B  Model Extensions

This appendix covers several model extensions. First, we study equilibrium dynamics under a benchmark model of Bayesian model updating and contrast these predictions with those obtained in our main analysis (B.1). Second, we theoretically characterize and quantify the normative implications of narrative fluctuations (B.2). Third, fourth, fifth, and sixth we extend the baseline model to respectively incorporate a continuum of different levels of optimism (B.3), narratives about idiosyncratic fundamentals (B.4), multi-dimensional narratives and persistent fundamentals (B.5), and narrative updating that depends on idiosyncratic fundamentals (B.6). In each case, we characterize equilibrium dynamics and show how our main theoretical insights extend. Seventh, we show how endogenous cycles and chaotic dynamics can obtain when agents are contrarian and implement an empirical test for their presence (B.7). Eighth, we highlight the role of higher-order beliefs and show how our analysis could generalize to other settings by deriving a similar law of motion for optimism in abstract, linear beauty contest games à la Morris and Shin (2002) (B.8). Finally, we sketch an extension of our abstract framework to allow for persistent idiosyncratic states and adjustment costs and discuss the implications for our measurement (B.9).

B.1 Comparison to the Bayesian Benchmark

Consider an alternative model in which each agent $i$ initially believes the optimistic model is correct with probability $\lambda_{i0} \in (0,1)$, and subsequently updates this probability by observing aggregate output and aggregate optimism and applying Bayes’ rule under rational expectations. Formally, this corresponds to the following law of motion for $Q_t$:

$$Q_{t+1} = \int_{[0,1]} P_i[\mu = \mu_0 | \{\log Y_j, Q_j\}_{j=0}^t] \, di$$

(121)

where $P_i[\mu = \mu_0 | \emptyset] = \lambda_{i0}$ for some $\lambda_{i0} \in (0,1)$ for all $i \in [0,1]$, and conditional probabilities are computed under rational expectations with knowledge of $\{\lambda_{i0}\}_{i \in [0,1]}$. We define the log-odds ratio of an agent’s belief as $\Omega_{it} = \log \frac{\lambda_{it}}{1-\lambda_{it}}$. The following Proposition characterizes the dynamics of agents’ subjective models under the Bayesian benchmark:

Proposition 8 (Dynamics under the Bayesian Benchmark). Each agent’s log-odds ratio follows a random walk with drift, or $\Omega_{i,t+1} = \Omega_{i,t} + a + \xi_t$, where $a = E_H \left[ \frac{(\log(\theta_i - \mu_P))^2 - (\log(\theta_i - \mu_O))^2}{\sigma^2} \right]$ and $\xi_t$ is an IID, mean-zero random variable. The economy converges almost surely to either extreme optimism ($a > 0$) or extreme pessimism ($a < 0$). The dynamics of the economy are
asymptotically described by:

\[ \log Y_t = \begin{cases} 
  a_0 + a_1 \log \theta_t & \text{if } a < 0, \\
  a_0 + a_1 \log \theta_t + f(1) & \text{if } a > 0.
\end{cases} \]  

(122)

Thus, the economy does not feature steady state multiplicity, hump-shaped or discontinuous IRFs, or the possibility for boom-bust cycles.

**Proof.** The equilibrium Characterization of Proposition 1 still holds. Moreover, \( Q_0 \) is known to all agents. Thus, they can identify \( \theta_0 \) as:

\[ \theta_0 = \frac{\log Y_0 - a_0 - f(Q_0)}{a_1} \]  

(123)

Thus, we have that \( \lambda_{i_1} = \mathbb{P}[\mu = \mu_O|\theta_0, \lambda_{i_0}] \). Moreover, all agents know that \( Q_1 = \int_{[0,1]} \lambda_{i_1} \, di \). Thus, agents can sequentially identify \( \theta_t \) by observing only \( \{Y_j : j \leq t\} \) (and not \( \{Q_j : j \leq t\} \)) by computing:

\[ \theta_t = \frac{\log Y_t - a_0 - f(Q_t)}{a_1} \]  

(124)

Thus, we can describe the evolution of agents’ beliefs by computing:

\[ \lambda_{i,t+1} = \mathbb{P}[\mu = \mu_O|\theta_t, \lambda_{i,t}] = \mathbb{P}[\mu = \mu_O|\theta_t] = \frac{f_O(\theta_t) \lambda_{i,t}}{f_O(\theta_t) \lambda_{i,t} + f_P(\theta_t)(1 - \lambda_{i,t})} \]  

(125)

By application of Bayes rule, we obtain:

\[ \lambda_{i,t+1} = \mathbb{P}[\mu = \mu_O|\theta_t, \lambda_{i,t}] = \frac{f_O(\theta_t) \lambda_{i,t}}{f_O(\theta_t) \lambda_{i,t} + f_P(\theta_t)(1 - \lambda_{i,t})} \]  

(126)

which implies that:

\[ \frac{\lambda_{i,t+1}}{1 - \lambda_{i,t+1}} = \frac{f(\log \theta_t|\mu = \mu_O)}{f(\log \theta_t|\mu = \mu_P)1 - \lambda_{i,t}} \lambda_{i,t} \]

\[ = \exp \left\{ \frac{(\log \theta_t - \mu_P)^2 - (\log \theta_t - \mu_O)^2}{\sigma^2} \right\} \frac{\lambda_{i,t}}{1 - \lambda_{i,t}} \]  

(127)

Defining \( \Omega_{i,t} = \log \frac{\lambda_{i,t}}{1 - \lambda_{i,t}} \) and \( a = \mathbb{E}_H \left[ \frac{(\log \theta_t - \mu_P)^2 - (\log \theta_t - \mu_O)^2}{\sigma^2} \right] \) and \( \xi_t = \frac{(\log \theta_t - \mu_P)^2 - (\log \theta_t - \mu_O)^2}{\sigma^2} - a \), we then have that:

\[ \Omega_{i,t+1} = \Omega_{i,t} + \frac{(\log \theta_t - \mu_P)^2 - (\log \theta_t - \mu_O)^2}{\sigma^2} - a + \xi_t \]  

(128)
which is a random walk with drift, with the drift and stochastic increment claimed in the statement. Iterating, dividing by \( t \), and applying the law of large numbers, we obtain:

\[
\frac{\Omega_{i,t}}{t} = \frac{1}{t} \Omega_{i,0} + \frac{t-1}{t} a + \frac{1}{t} \sum_{i=1}^{t} \xi_i \to \text{a.s.} a
\]  

(129)

Hence, almost surely, we have that \( Q_t \to 1 \) if \( a > 0 \) and \( Q_t \to 0 \) if \( a < 0 \).

Hence, the dynamics are asymptotically described by Proposition 1 with \( Q_t = 1 \) if \( a > 0 \) and \( Q_t = 0 \) if \( a < 0 \). The resulting properties for output follow immediately from combining this characterization for \( Q_t \) with the characterization in our main analysis of equilibrium output conditional on optimism and fundamentals (Proposition 1), which continues to hold in the model of this appendix.

The optimist fraction \( Q \) converges to either 0 or 1 in the long run because one model is unambiguously better-fitting, and this will be revealed with infinite data. Moreover, the log-odds ratio converges linearly and so the odds ratio in favor of the better fitting model converges exponentially quickly. Thus the Bayesian benchmark model makes a prediction that is at odds with our finding of cyclical dynamics for aggregate optimism (Figure 1), and moreover, in the long run, rules out the features of macroeconomic dynamics that we derive in Section 6 as consequences of the endogenous evolution of narrative optimism.

**B.2 Welfare Implications**

In this appendix, we derive the normative implications of narratives for the economy.

**Theory.** The following result characterizes welfare along any path for the fraction of optimists in the population and the conditions under which a steady state of extreme optimism is preferred to one of extreme pessimism:

**Proposition 9 (Narratives and Welfare).** For any path of aggregate optimism \( Q = \{Q_t\}_{t=0}^{\infty} \), aggregate welfare is given by

\[
U(Q) = U^*_C \sum_{t=0}^{\infty} \beta^t \exp \{(1 - \gamma) f(Q_t)\} \\
- U^*_L \sum_{t=0}^{\infty} \beta^t (Q_t \exp \{(1 + \psi)d_2 + (1 - Q_t)\} \exp \{(1 + \psi)d_3 f(Q_t)\}
\]  

(130)

for some positive constants \( U^*_C, U^*_L, d_2 \) and \( d_3 \) that are provided in the proof of the result.

Thus, there is higher welfare in an optimistic steady state than in a pessimistic steady state.
if and only if
\[
\frac{U_C^*}{U_L^*} \times \frac{\exp \{(1 - \gamma) f(1)\} - 1}{\exp \{(1 + \psi) (d_2 + d_3 f(1))\} - 1} > 1
\]  
(131)

Moreover, when the pessimistic narrative is correctly specified, extreme optimism is welfare-equivalent to an ad valorem price subsidy for intermediate goods producers of:
\[
\tau^* = \exp \left\{(1 - \omega) \left(\frac{1 + \psi - \alpha}{\alpha} + \frac{1}{\epsilon}\right) f(1)\right\} - 1
\]  
(132)

**Proof.** We have that welfare for any path of optimism \(Q = \{Q_t\}_{t \in \mathbb{N}}\) is given by:
\[
U(Q) = \sum_{t=0}^{\infty} \beta^t \left( \mathbb{E}_H \left[ C_t(Q_t, \theta_t)^{1-\gamma} \right] - \mathbb{E}_H \left[ \int_{[0,1]} L_{it}(\gamma_i, s_{it}, Q_t)^{1+\psi} \, di \right] \right)
\]  
(133)

By market clearing, we have that \(C_t = Y_t\) for all \(t\). Thus, using the formula for equilibrium aggregate output from Proposition 1 and our assumption that \(\log \theta_t\) is Gaussian under \(H\), we have that the consumption component of welfare is given by:
\[
\mathbb{E}_H \left[ \frac{C_t^{1-\gamma}(Q_t, \theta_t)}{1 - \gamma} \right] = \mathbb{E}_H \left[ \frac{1}{1 - \gamma} \exp \{(1 - \gamma) \log Y(Q_t, \theta)\} \right]
\]  
\[
= \mathbb{E}_H \left[ \frac{1}{1 - \gamma} \exp \{(1 - \gamma) (a_0 + a_1 \log \theta + f(Q_t))\} \right]
\]  
\[
= \frac{1}{1 - \gamma} \exp \left\{(1 - \gamma) (a_0 + a_1 \mu_H + f(Q_t)) + \frac{1}{2} a_1^2 \sigma_H^2 \right\}
\]  
(134)
\[
= \frac{1}{1 - \gamma} \exp \left\{(1 - \gamma) (a_0 + a_1 \mu_H) + \frac{1}{2} a_1^2 \sigma_H^2 \right\} \exp \{(1 - \gamma) f(Q_t)\}
\]  
\[
= U_C^* \exp \{(1 - \gamma) f(Q_t)\}
\]

From Proposition 1, we moreover have that labor employed by each firm can be written as:
\[
L_{it} = d_1 \log \theta_t + d_2 \lambda_t + d_3 f(Q_t) + v_{it}
\]  
(135)

where \(v_{it}\) is Gaussian and IID over \(i\). Hence given \(\theta\) and \(Q_t\):
\[
\int_{[0,1]} \frac{L_{it}(\gamma_i, s_{it}, Q_t)^{1+\psi}}{1 + \psi} \, di
\]  
\[
= \frac{1}{1 + \psi} \left( Q_t \exp \{(1 + \psi) d_2\} + (1 - Q_t) \right)
\]  
(136)
\[
\times \exp \left\{(1 + \psi) (d_1 \log \theta + \mu_v + d_3 f(Q_t)) + \frac{1}{2} (1 + \psi)^2 \sigma_v^2 \right\}
\]
Hence, the expectation over $\theta$ is given by:

$$\mathbb{E}_H \left[ \int_{[0,1]} \frac{L_{it}(\gamma_i, s_{it}, Q_t)^{1+\psi}}{1+\psi} \, di \right]$$

$$= \frac{1}{1+\psi} (Q_t \exp\{(1+\psi)d_2\} + (1-Q_t)) \times \exp\{(1+\psi)d_3 f(Q_t)\} \exp\left\{ (1+\psi)(d_1\mu_H + \mu_v) + \frac{1}{2}(1+\psi)^2(\sigma_v^2 + d_1^2\sigma_H^2) \right\}$$

$$= U^*_L (Q_t \exp\{(1+\psi)d_2\} + (1-Q_t)) \exp\{(1+\psi)d_3 f(Q_t)\}$$  \hspace{0.5cm} (137)

And so total welfare under narrative path $Q$ is given by:

$$U(Q) = U^*_C \sum_{t=0}^{\infty} \beta^t \exp\{(1-\gamma)f(Q_t)\}$$

$$- U^*_L \sum_{t=0}^{\infty} \beta^t (Q_t \exp\{(1+\psi)d_2\} + (1-Q_t)) \exp\{(1+\psi)d_3 f(Q_t)\}$$  \hspace{0.5cm} (138)

The final inequality follows by noting that $f(0) = 0$ and rearranging this expression.

Now consider the benchmark model but where, without loss of generality, all agents are pessimistic $Q_t = 0$ and a planner levies an ad valorem subsidy. That is, when the consumer price is $p^C_{it} = Y_t^\frac{1}{\epsilon} x_{it}^{-\frac{1}{\epsilon}}$, the price received by the producer is $p^P_{it} = (1+\tau)p^C_{it}$. Under this subsidy, each producer’s first-order condition is:

$$\log x_{it} = \frac{1}{1+\frac{\omega-\alpha}{\alpha}} + \frac{1}{\epsilon} \left( \log \left( \frac{1-\frac{1}{\epsilon}}{1+\frac{1+\psi}{\alpha}} \right) - \log \mathbb{E}_t \left[ \exp \left\{ -\frac{1+\psi}{\alpha} \log \theta_{it} \right\} \right] \right)$$

$$+ \log \mathbb{E}_t \left[ \exp \left\{ \left( \frac{1}{\epsilon} - \gamma \right) \log Y_t \right\} \right] + \Xi(\tau)$$  \hspace{0.5cm} (139)

where $\Xi(\tau) = \frac{1}{1+\frac{\omega-\alpha}{\alpha + \tau}} \log(1+\tau)$. By identical arguments to Proposition 1, we have that there is a unique quasi-linear equilibrium, where:

$$\log Y(\theta, \tau) = a_0 + a_1 \log \theta + \frac{1}{1-\omega} \Xi(\tau)$$  \hspace{0.5cm} (140)

and $a_0$ and $a_1$ are as in Proposition 1. Hence, in this equilibrium we have that:

$$\log x_{it}(\tau) = \log x_{it}(0) + \frac{1}{1-\omega} \Xi(\tau)$$  \hspace{0.5cm} (141)
Which implies that:

\[ \log L_{it}(\tau) = \log L_{it}(0) + \frac{1}{\alpha} \frac{1}{1 - \omega} \Xi(\tau) \]  

(142)

And so, welfare under the subsidy \( \tau \) is given by:

\[
U(\tau) = U_C^* \sum_{t=0}^{\infty} \beta^t \exp \left\{ (1 - \gamma) \frac{1}{1 - \omega} \Xi(\tau) \right\} 
- U_L^* \sum_{t=0}^{\infty} \beta^t \exp \left\{ (1 + \psi)d_3 \frac{1}{1 - \omega} \Xi(\tau) \right\}
\]  

(143)

as \( d_3 = \frac{1}{\alpha} \). Hence:

\[ U(1) = U(\tau^*) \]  

(144)

where \( \tau^* \) is such that \( \frac{1}{1 - \omega} \Xi(\tau^*) = f(1) \). Hence:

\[ \tau^* = \exp \left\{ (1 - \omega) \left( \frac{1 + \psi - \alpha}{\alpha} + \frac{1}{\epsilon} \right) f(1) \right\} - 1 \]  

(145)

Completing the proof. \( \square \)

This result sheds light on the potential for non-fundamental optimism to increase aggregate welfare. In the presence of the product market monopoly and labor market monopsony distortions, intermediates goods firms under-hire labor and under-produce goods. As a result, if irrational optimism causes them to produce more output, but not so much that the household over-supplies labor, then it has the potential to be welfare improving. The final part of the proposition then reduces this question to assessing if the implied optimism-equivalent subsidy is less than the welfare-optimal subsidy. Thus, optimism in the economy can serve the role of undoing monopoly frictions and thereby has the potential to be welfare-improving, even when misspecified.

**Quantification.** Proposition 9 can be directly applied in our numerical calibration from Section 7 to calculate the welfare effects of narrative optimism without approximation. We calculate the average payoff of the representative household under three scenarios. The first corresponds to the calibrated narrative dynamics in simulation, under the assumption that the pessimistic model is correctly specified.\(^{37}\) The second is a counterfactual scenario with permanent extreme optimism, or \( Q_t \equiv 1 \) for all \( t \). The third is a counterfactual scenario with permanent extreme pessimism, or \( Q_t \equiv 0 \) for all \( t \), and an *ad valorem* subsidy of \( \tau \) to all producers. We use the third scenario to translate the first and second into payoff-equivalent

---

\(^{37}\) Relative to the positive analysis, the normative analysis requires two additional model parameters. We set the idiosyncratic component of productivity to have unit mean and zero variance.

84
subsidies. We find that both contagious and extreme optimism are welfare-increasing relative to extreme pessimism in autarky \((i.e., \tau = 0)\). In payoff units, they correspond respectively to equivalent subsidies of 1.33\% and 2.59\%. Our finding of an overall positive welfare effect for contagious optimism suggests that, in our macroeconomic calibration, losses from inducing misallocation are more than compensated by level increases in output.

### B.3 Continuous Narratives

Our main analysis featured two levels of optimism. However, much of our analysis generalizes to a setting with a continuum of levels of optimism. For simplicity, in this section we abstract from optimism shocks. The model is as in Section 5, but now \(\mu \in [\mu_P, \mu_O]\) and the distribution of narratives is given by \(Q_t \in \Delta([\mu_P, \mu_O])\). The probabilistic transition between models is now given by a Markov kernel \(P: [\mu_P, \mu_O] \times Y \times \Delta^2([\mu_P, \mu_O]) \to \Delta([\mu_P, \mu_O])\) where \(P_{\mu'}(\mu, \log Y, Q_t)\) is the density of agents who have model \(\mu\) who switch to \(\mu'\) when aggregate output is \(Y\) and the distribution of narratives is \(Q_t\).

**Characterizing Equilibrium Output.** By modifying the guess-and-verify arguments that underlie Proposition 1, we can obtain an almost identical representation of equilibrium aggregate output:

**Proposition 10 (Equilibrium Characterization with Continuous Narratives).** There exists a quasi-linear equilibrium:

\[
\log Y(\log \theta_t, Q_t) = a_0 + a_1 \log \theta_t + f(Q_t)
\]  

Moreover, the density of narratives evolves according to the following difference equation:

\[
dQ_{t+1}(\mu') = \int_{\mu_P}^{\mu_O} P_{\mu'}(\mu, a_0 + a_1 \log \theta_t + f(Q_t), Q_t)dQ_t(\mu) \tag{147}
\]

**Proof.** By appropriately modifying the steps of the proof of Proposition 1, the result follows. Throughout, simply replace \(\lambda_{it} \mu_O + (1 - \lambda_{it}) \mu_P\) with \(\tilde{\mu}_{it} \sim Q_t\) and \(\lambda_{it}\) with \(\tilde{\mu}_{it}\) as appropriate. The proof follows as written until the aggregation step. At this point, we instead obtain:

\[
\log Y_t = \delta_t(\mu_P) + \frac{1}{2} \frac{\epsilon - 1}{\epsilon} \sigma^2 + \frac{\epsilon}{\epsilon - 1} \log \left( \int_{\mu_P}^{\mu_O} \exp \left\{ \frac{\epsilon - 1}{\epsilon} (\delta_t(\tilde{\mu}) - \delta_t(\mu_P)) \right\} dQ_t(\tilde{\mu}) \right) \tag{148}
\]

where \(\delta_t(\mu_P) = \delta_t(0)\) and \(\delta_t(\tilde{\mu}) - \delta_t(\mu_P) = \alpha \delta^{OP} \frac{\tilde{\mu} - \mu_P}{\mu_O - \mu_P}\). Hence, we have that \(a_0\) and \(a_1\) are
as in Proposition 1 and $f$ is instead given by:

$$f(Q) = \frac{\epsilon}{\epsilon - 1} \log \left( \int_{\mu_P}^{\mu_O} \exp \left\{ \frac{\epsilon - 1}{\epsilon} \alpha \delta_{OP} (\frac{\mu - \mu_P}{\mu_O - \mu_P}) \right\} dQ(\tilde{\mu}) \right)$$  \hspace{1cm} (149)$$

Completing the proof.

Importantly, observe that we still obtain a marginal representation in terms of the partial equilibrium effect of going from full pessimism to full optimism on hiring $\delta_{OP}$, as we have empirically estimated.

**Equilibrium Dynamics.** We have seen that a continuum of models poses no difficulty for the static analysis. The challenge for the dynamic analysis is that the state variable, the evolution of which is fully characterized by Proposition 10, is now infinite-dimensional. This notwithstanding, by use of approximation arguments, we can reduce the dynamics to an essentially identical form to that which we have studied in the main text.

To this end, define the cumulant generating function (CGF) of the cross-sectional distribution of narratives as:

$$K_Q(\tau) = \log \left( \mathbb{E}_Q[\exp\{\tau \tilde{\mu}\}] \right)$$  \hspace{1cm} (150)$$

We therefore have that $\log \left( \mathbb{E}_Q[\exp\{\tau (\tilde{\mu} - z)\}] \right) = K_Q(\tau) - \tau z$. It follows by Equation 149 that:

$$f(Q) = \frac{\epsilon}{\epsilon - 1} \left[ K_Q \left( \frac{\epsilon - 1}{\epsilon} \alpha \delta_{OP} \frac{1}{\mu_O - \mu_P} \right) - \frac{\epsilon - 1}{\epsilon} \alpha \delta_{OP} \frac{\mu_P}{\mu_O - \mu_P} \right]$$  \hspace{1cm} (151)$$

By Maclaurin series expansion, we can express the CGF to first-order as:

$$K_Q(\tau) = \mu_Q \tau + O(\tau^2)$$  \hspace{1cm} (152)$$

We therefore have that:

$$f(Q) = \frac{1}{1 - \omega} \alpha \delta_{OP} \frac{\mu_Q - \mu_P}{\mu_O - \mu_P} + O \left( \left( \frac{\epsilon - 1}{\epsilon} \alpha \delta_{OP} \frac{1}{\mu_O - \mu_P} \right)^2 \right)$$  \hspace{1cm} (153)$$

We now can express the static, general equilibrium effects in terms of mean of the narrative distribution. With some abuse of notation, we now write $f(\mu_Q) = f(Q)$. Of course, this CGF-based approach would allow one to consider higher-order effects through the variance, skewness, kurtosis, and higher cumulants as desired.

In the next steps, we provide conditions on updating that allow us to express the dynamics solely in terms of the mean of the narrative distribution. To do this, we assume that $P_\nu(\mu, \log Y, Q) = P_{\nu'}(\mu'', \log Y, \mu_Q)$ for all $Q \in \Delta^2([\mu_P, \mu_O])$ and all $\mu, \mu', \mu'' \in [\mu_P, \mu_O]$. 86
This is tantamount to assuming no stubbornness (all agents update the same regardless of the model they start with) and that contagiousness only matters via the mean. Under this assumption, we can write $P_\mu(\log Y(\log \theta, \mu_Q), \mu_Q)$ and express the difference equation as:

$$dQ_{t+1}(\mu') = \int_{\mu_P}^{\mu_O} P_\mu'(a_0 + a_1 \log \theta_t + f(\mu_Q,t), \mu_Q,t)dQ_t(\mu)$$

$$= P_\mu'(a_0 + a_1 \log \theta_t + f(\mu_Q,t), \mu_Q,t)$$

(154)

It then suffices to take the mean of $Q_{t+1}$ to express the system in terms of the one-dimensional state variable $\mu_{Q,t}$:

$$\mu_{Q,t+1} = T(\mu_{Q,t}, \theta_t) = \int_{\mu_P}^{\mu_O} \mu_0 P_\mu'(a_0 + a_1 \log \theta_t + f(\mu_Q,t), \mu_Q,t)d\mu'$$

(155)

Which is simply a continuous state analog of the difference equation expressed in Corollary 2 expressed in terms of average beliefs.

**Steady State Multiplicity.** We now obtain the analogous characterization of extremal steady state multiplicity in this setting, *i.e.*, when it is possible that all agents being maximally pessimistic and all agents being maximally optimistic are simultaneously deterministic steady states. To this end, define the following two inverses:

$$\hat{P}^{-1}(x; \mu_Q) = \sup\{Y : P(Y,Q) = \delta_x\}$$

$$\hat{P}^{-1}(x; \mu_Q) = \inf\{Y : P(Y,Q) = \delta_x\}$$

(156)

where $\delta_x$ denotes the Dirac delta function on $x$. We define analogous objects to the previous $\theta_O$ and $\theta_P$:

$$\theta_O = \exp \left\{ \hat{P}^{-1}(\mu_O; \mu_Q) - a_0 - f(1) \right\} \quad \theta_P = \exp \left\{ \hat{P}^{-1}(\mu_P; \mu_P) - a_0 - f(1) \right\}$$

(157)

The following result establishes that these thresholds characterize extremal multiplicity:

**Proposition 11** (Steady State Multiplicity with Continuous States). Extreme optimism and pessimism are simultaneously deterministic steady states for $\theta$ if and only if $\theta \in [\theta_O, \theta_P]$, which is non-empty if and only if

$$\hat{P}^{-1}(\mu_O; \mu_Q) - \hat{P}^{-1}(\mu_P; \mu_P) \leq f(1)$$

(158)

**Proof.** This follows exactly the same steps as the proofs of Proposition 2 and Corollary 3, replacing the appropriate inverses defined above. □
Thus, the same conditions that give rise to multiplicity with binary narratives obtain with a continuum of levels of optimism. Indeed, observe that restricting to first-order approximations above was unnecessary. We could have considered an arbitrary order, say $k$, of approximation of the CGF and obtained a system of difference equations for the first $k$ cumulants. Proposition 11 would still hold as written, as under the extremal steady states, all higher cumulants are identically zero and remain so under the provided condition. Naturally, however, the general dynamics only reduce to those resembling the simple model under the first-order approximation. Nevertheless, we observe that this is a first-order approximation to the exact equilibrium dynamics and not simply an approximation of the dynamics of an approximate equilibrium.

### B.4 Narratives About Idiosyncratic Fundamentals

In the main analysis, we assumed that narratives described properties of aggregate fundamentals. In this section, we characterize equilibrium dynamics when narratives describe properties of idiosyncratic fundamentals. Concretely, we now instead suppose that all agents believe that $\log \theta_t \sim N(0, \sigma^2)$, or agree about the distribution of aggregate productivity. Moreover, as in the baseline, all agents believe that others’ idiosyncratic productivity follows $\log \tilde{\theta}_{jt} \sim N(0, \sigma^2_{\theta})$ for all $j \neq i$. However, agents disagree about the mean of their own idiosyncratic productivity: optimistic agents believe that $\log \tilde{\theta}_{it} \sim N(\mu_O, \sigma^2_{\theta})$ while pessimistic agents believe that $\log \tilde{\theta}_{it} \sim N(\mu_P, \sigma^2_{\theta})$. The rest of the model is identical.

In this context, dynamics are identical conditional on the static relationship between output and narratives. Moreover, the static relationship between output and narratives is now identical (up to a constant) conditional on estimating the partial equilibrium effect of optimism on hiring. This is formalized by the following result:

**Proposition 12** (Equilibrium Characterization with Narratives About Idiosyncratic Fundamentals). There exists a unique equilibrium such that:

$$
\log Y(\log \theta_t, Q_t) = \tilde{a}_0 + a_1 \log \theta_t + \tilde{f}(Q_t) \quad (159)
$$

for coefficients $\tilde{a}_0$ and $a_1 > 0$, and a strictly increasing function $f$, where $a_1$ is identical to that from Proposition 1 and

$$
\tilde{f}(Q) = \frac{\epsilon - \frac{1}{\epsilon}}{\epsilon - \frac{1}{\epsilon} \gamma - \frac{1}{\epsilon} \delta^{OP}} \log \left( 1 + Q \left[ \exp \left( \frac{\epsilon - 1}{\epsilon} \alpha \delta^{OP} \right) - 1 \right] \right) \quad (160)
$$

where $\delta^{OP}$ is defined in Equation 161.
Proof. The proof follows exactly the steps of the proof of Proposition 1 where the aggregate narrative is replaced with an idiosyncratic one. To be concrete, the computation of \( \log \mathbb{E}_{it} \left[ \theta_{it}^{1+\psi} \right] \) and the method of aggregation are identical to those in the proof of Proposition 1. The only difference is in the computation of \( \log \mathbb{E}_{it} \left[ Y_t^{1/2} \right] \). Now, Equation 74 differs in that \( \mu_{it} = \log \gamma_i + \kappa s_{it} \). Tracking this through to Equation 78, lines 1, 2, 3, and 5 are identical and line 4 differs only in that the term \((1-\kappa)[\lambda_{it}\mu_O + (1-\lambda_{it})\mu_P]\) is now set equal to zero. The analysis then follows up to Equation 83, at which point we have that the exact formula for \( \delta^{OP} \) changes and is now given by:

\[
a_{OP}^{\tilde{\delta}} = \frac{1+\psi}{1+\psi-a} + \frac{1}{\epsilon} (1-\kappa)(\mu_O - \mu_P) \tag{161}
\]

The formula for \( \delta_t(0) \) is identical except for in the second line where the term \( a_1(1-\kappa)\mu_P \) is now equal to zero. The formula for \( a_1 \) remains the same. Conditional on \( \tilde{\delta}^{OP} \), the formula for \( f \) remains the same. The formula for \( a_0 \) is identical except for the second line where the term \( (1/\epsilon-\gamma)a_1(1-\kappa)\mu_P \) is now equal to zero.

This Proposition makes clear that output differs in this case only up to an intercept and in changing the mapping from structural parameters to the partial-equilibrium effect of optimism on hiring. Nonetheless, interpreted via the model above, our empirical exercise directly identifies the new-relevant parameter \( \tilde{\delta}^{OP} \). As a result, neither our theoretical nor quantitative analysis is sensitive to making narratives be about idiosyncratic conditions. The only difference is that the point calibrations for \( \kappa \) and \( (\mu_O - \mu_P) \) would change, while the aggregate dynamics would remain identical.

### B.5 Multi-Dimensional Narratives and Persistent States

Our baseline model featured two narratives regarding the mean of fundamentals and transitory fundamentals, but we live in a world of many competing narratives regarding many aspects of reality and potentially persistent fundamentals. In this extension, we broaden our analysis to study a class of three-dimensional narratives, which is essentially exhaustive within the Gaussian class. For simplicity, we abstract from narrative shocks in this analysis. Concretely, suppose that agents believe that the aggregate component of fundamentals follows:

\[
\log \theta_t = (1-\rho)\mu + \rho \log \theta_{t-1} + \sigma \nu_t \tag{162}
\]

with \( \nu_t \sim N(0,1) \) and IID. Narratives now correspond to a vector of \((\mu, \rho, \sigma)\), indexing the mean, persistence and variance of the process for fundamentals. The set of narratives can
therefore be represented by \(\{(\mu_k, \rho_k, \sigma_k)\}_{k \in K}\). We restrict that agents place Dirac weights on this set, so that they only ever believe one narrative at a time, and let \(Q_{t,k}\) be the fraction of agents who believe narrative \((\mu_k, \rho_k, \sigma_k)\) at time \(t\). Finally, we assume that agents face the same signal-to-noise ratio \(\kappa\), regardless of the narrative that they hold.\(^{38}\) Together, these assumptions ensure that agents’ posteriors are normal and place a common weight on narratives when agents form their expectations of fundamentals.

By modifying the functional guess-and-verify arguments from Proposition 1, we characterize equilibrium output in this setting in the following result:

**Proposition 13** (Equilibrium Characterization with Multi-Dimensional Narratives and Persistence). There exists a quasi-linear equilibrium:

\[
\log Y(\log \theta_t, \log \theta_{t-1}, Q_t) = a_0 + a_1 \log \theta_t + a_2 \log \theta_{t-1} + f(Q_t, \theta_{t-1}) \tag{163}
\]

for some \(a_1 > 0\), \(a_2 \geq 0\), and \(f\). In this equilibrium, the distribution of narratives in the population evolves according to:

\[
Q_{t+1,k} = \sum_{k' \in K} Q_{t,k'} P_{k'}(k, a_0 + a_1 \log \theta_t + a_2 \log \theta_{t-1} + f(Q_t, \theta_{t-1}), Q_t) \tag{164}
\]

**Proof.** We follow the same steps as in the proof of Proposition 1, appropriately adapted to this richer setting. First, we guess an equilibrium of the form:

\[
\log Y(\log \theta_t, \log \theta_{t-1}, Q_t) = a_0 + a_1 \log \theta_t + a_2 \log \theta_{t-1} + f(Q_t, \theta_{t-1}) \tag{165}
\]

To verify that this is an equilibrium, we need to compute agents’ best replies under this conjecture, aggregate them, and show that they are consistent with this guess once aggregated.

We first find agents’ posterior beliefs given narrative weights. Let \(E\) denote the standard basis for \(\mathbb{R}^K\) with \(k\)-th basis vector denoted by

\[
e_k = \{0, \ldots, 0, 1, 0, \ldots, 0\}_{k-1} \quad (166)
\]

We have that \(\lambda_{it} = e_k\) for some \(k \leq K\). Under this narrative loading, we have that agent’s posteriors are given by:

\[
\log \theta_{it} | \lambda_{it}, s_{it} \sim N \left( \log \gamma_i + \kappa s_{it} + (1 - \kappa) \mu(\lambda_{it}, \theta_{t-1}), \sigma_{\theta_{it}}^2(\lambda_{it}) + \sigma^2 \right) \tag{167}
\]

\(^{38}\)Formally, this means that the variance of the noise in agents’ signals satisfies \(\sigma_{e,k}^2 \propto \sigma_k^2\) across narratives.
with:

\[
\mu(e_k, \theta_{t-1}) = (1 - \rho_k)\mu_k + \rho_k \log \theta_{t-1}
\]

\[
\sigma^2_{\theta|s}(e_k) = \frac{1}{\sigma^2_k} + \frac{1}{\sigma^2_{e,k}} \quad \kappa = \frac{1}{1 + \sigma^2_{e,k}/\sigma^2_k}
\]

(168)

for all \(k \leq K\), where \(\kappa\) does not depend on \(k\) as \(\sigma^2_{e,k} \propto \sigma^2_k\). Hence, we can compute agents’ best replies by evaluating:

\[
\log \mathbb{E}_{it} \left[ \theta_{it}^{\frac{1}{1 + \psi - \alpha}} \right] = -\frac{1 + \psi}{\alpha} \left( \log \gamma_i + \kappa s_{it} + (1 - \kappa)\mu(\lambda_{it}, \theta_{t-1}) \right) + \frac{1}{2} \left( \frac{1 + \psi}{\alpha} \right)^2 \left( \sigma^2_{\theta|s}(\lambda_{it}) + \sigma^2_{\hat{\theta}} \right)
\]

(169)

\[
\log \mathbb{E}_{it} \left[ Y_t^{\frac{1}{1 - \gamma}} \right] = \left( \frac{1}{\epsilon} - \gamma \right) \left( a_0 + a_1 (\kappa s_{it} + (1 - \kappa)\mu(\lambda_{it}, \theta_{t-1})) + a_2 \log \theta_{t-1} + f(Q_t, \theta_{t-1}) \right) + \frac{1}{2} \left( \frac{1}{\epsilon} - \gamma \right)^2 a_1^2 \sigma^2_{\theta|s}(\lambda_{it})
\]

(170)

By substituting this into agents’ best replies, we obtain:

\[
\log x_{it} = \frac{1}{1 + \psi - \alpha} + \frac{1}{\epsilon} \left[ \log \left( \frac{1 - \frac{1}{\epsilon}}{1 + \psi - \alpha} \right) + \frac{1 + \psi}{\alpha} \left( \log \gamma_i + \kappa s_{it} + (1 - \kappa)\mu(\lambda_{it}, \theta_{t-1}) \right) \right]
\]

\[
- \frac{1}{2} \left( \frac{1 + \psi}{\alpha} \right)^2 \left( \sigma^2_{\theta|s}(\lambda_{it}) + \sigma^2_{\hat{\theta}} \right)
\]

\[
+ \left( \frac{1}{\epsilon} - \gamma \right) \left[ a_0 + a_1 (\kappa s_{it} + (1 - \kappa)\mu(\lambda_{it}, \theta_{t-1})) + a_2 \log \theta_{t-1} + f(Q_t, \theta_{t-1}) \right]
\]

\[
+ \frac{1}{2} \phi_0^2 \left( \frac{1}{\epsilon} - \gamma \right)^2 \sigma^2_{\theta|s}(\lambda_{it})
\]

(171)

which we observe is conditional normally distributed as \(\log x_{it} | \lambda_{it} \sim N(\delta_t(\lambda_{it}), \sigma^2)\) with \(\sigma^2\)
as in Equation 79 and:

\[
\delta_t(e_k) = \frac{1}{1 + \psi - \alpha} \left[ \log \left( \frac{1 - \frac{1}{\epsilon}}{1 + \psi - \alpha} \right) + \frac{1 + \psi}{\alpha} \log \gamma_i + \kappa \log \theta_t + (1 - \kappa)\mu(e_k, \theta_{t-1}) \right]
\]

\[
- \frac{1}{2} \left( \frac{1 + \psi}{\alpha} \right)^2 \left( \sigma_{\theta_{it}}^2(e_k) + \sigma_{\theta_t}^2 \right)
\]

\[
+ \left( \frac{1}{\epsilon} - \gamma \right) \left[ a_0 + a_1 \left( \kappa \log \theta_t + (1 - \kappa)\mu(e_k, \theta_{t-1}) \right) + a_2 \log \theta_{t-1} + f(Q_t, \theta_{t-1}) \right]
\]

\[
+ \frac{1}{2} a_1^2 \left( \frac{1}{\epsilon} - \gamma \right)^2 \sigma_{\theta_{it}}^2(e_k)
\]

(172)

for all \( k \leq K \). Aggregating these best replies, using Equation 80, we obtain that:

\[
\log Y_t = \frac{\epsilon}{\epsilon - 1} \log \mathbb{E}_t \left[ \mathbb{E}_t \left[ \exp \left\{ \frac{\epsilon - 1}{\epsilon} \log x_{it} \right\} | \lambda_{it} \right] \right]
\]

\[
= \frac{\epsilon}{\epsilon - 1} \log \left( \sum_k Q_{t,k} \exp \left\{ \frac{\epsilon - 1}{\epsilon} \delta_t(e_k) + \frac{1}{2} \left( \frac{\epsilon - 1}{\epsilon} \right)^2 \sigma^2 \right\} \right)
\]

\[
= \delta_t(e_1) + \frac{1}{2} \frac{\epsilon - 1}{\epsilon} \sigma^2 + \frac{\epsilon}{\epsilon - 1} \log \left( \sum_k Q_{t,k} \exp \left\{ \frac{\epsilon - 1}{\epsilon} \left( \delta_t(e_k) - \delta_t(e_1) \right) \right\} \right)
\]

(173)

where \( \sigma^2 \) is a constant, \( \delta_t(e_1) \) depends linearly on \( \log \theta_t \) and \( \log \theta_{t-1} \) and \( \delta_t(e_k) - \delta_t(e_1) \) does not depend on \( \log \theta_t \) for all \( k \leq K \) and can therefore be written as \( \delta_{k1}(\theta_{t-1}) \). Moreover, by matching coefficients, we obtain that \( a_1 \) is the same as in the proof of Proposition 1. And we find that \( f \) must satisfy:

\[
f(Q, \theta_{t-1}) = \frac{1 - \gamma}{1 + \psi - \alpha} f(Q, \theta_{t-1}) + \frac{\epsilon}{\epsilon - 1} \log \left( \sum_k Q_{t,k} \exp \left\{ \frac{\epsilon - 1}{\epsilon} \delta_{k1}(\theta_{t-1}) \right\} \right)
\]

(174)

and so:

\[
f(Q, \theta_{t-1}) = \frac{\epsilon - 1}{1 - \frac{1 - \gamma}{1 + \psi - \alpha} \frac{1}{\epsilon}} \log \left( \sum_k Q_{t,k} \exp \left\{ \frac{\epsilon - 1}{\epsilon} \delta_{k1}(\theta_{t-1}) \right\} \right)
\]

(175)

Completing the proof.

In the multidimensional narrative case with persistence, the past value of fundamentals interacts non-linearly with the cross-sectional narrative distribution in affecting aggregate output. However, without more structure, the properties of the dynamics generated by this
multi-dimensional system are essentially unrestricted.

B.6 Persistent Idiosyncratic Shocks and Belief Updating

We now extend the analysis from Section B.5 to the case where agents' idiosyncratic states drive narrative updating and are persistent. Concretely, in that setting, we let $P_{k'}$ depend on $(Y_t, Q_t, \tilde{\theta}_{it})$ and idiosyncratic productivity shocks evolve according to an AR(1) process:

$$\log \tilde{\theta}_{it} = \rho \log \tilde{\theta}_{it-1} + \zeta_{it}$$  \hspace{1cm} (176)

where $0 < \rho \tilde{\theta} < 1$ and $\zeta_{it} \sim N(0, \sigma^2_{\zeta})$. We let $F_{\tilde{\theta}}$ denote the stationary distribution of $\tilde{\theta}_{it}$, which coincides with the cross-sectional marginal distribution of $\tilde{\theta}_{it}$ for all $t \in \mathbb{N}$.

The additional theoretical complication these two changes induce is that the marginal distribution of narratives $Q_t$ is now insufficient for describing aggregate output. This is because narratives $\lambda_{it}$ and idiosyncratic fundamentals $\tilde{\theta}_{it}$ are no longer independent as $\lambda_{it}$ and $\tilde{\theta}_{it}$ both depend on $\tilde{\theta}_{it-1}$. The relevant state variable is now the joint distribution of narratives and idiosyncratic productivity $\tilde{Q}_t \in \Delta(\Lambda \times \mathbb{R})$. We denote the marginals as $Q_t$ and $F_{\tilde{\theta}}$, and the conditional distribution of narratives given $\tilde{\theta}$ as $\bar{Q}_{t,k|\tilde{\theta}} = \frac{Q_{t,k}(\tilde{\theta})}{f_{\tilde{\theta}}(\tilde{\theta})}$.

Proposition 14 (Equilibrium Characterization with Multi-Dimensional Narratives, Aggregate and Idiosyncratic Persistence, and Idiosyncratic Narrative Updating). There exists a quasi-linear equilibrium:

$$\log Y(\log \theta_t, \log \theta_{t-1}, \tilde{Q}_t) = a_0 + a_1 \log \theta_t + a_2 \log \theta_{t-1} + f(\tilde{Q}_t, \theta_{t-1})$$ \hspace{1cm} (177)

for some $a_1 > 0$, $a_2 \geq 0$, and $f$.

Proof. This proof follows closely that of Proposition 13. Under narrative loading $\lambda_{it}$, we have that the agent’s posterior regarding $\log \theta_{it}$ is given by:

$$\log \theta_{it|\tilde{\theta}_{it-1}, \lambda_{it}, s_{it}} \sim N \left( \log \gamma_i + \rho \log \tilde{\theta}_{it-1} + \kappa s_{it} + (1 - \kappa) \mu(\lambda_{it}, \theta_{t-1}), \sigma_{\tilde{\theta}|s}(\lambda_{it}) + \sigma^2_{\xi} \right)$$ \hspace{1cm} (178)

where $\mu(\lambda_{it}, \theta_{t-1})$, $\kappa$, and $\sigma^2_{\tilde{\theta}|s}(\lambda_{it})$ are as in Proposition 13. Then substitute $\log \gamma_i + \rho \log \tilde{\theta}_{it-1}$ for $\log \gamma_i$ and follow the Proof of Proposition 13 until the aggregation step (Equation 173).
We now instead have that:

\[
\begin{align*}
\log Y_t &= \frac{\epsilon}{\epsilon - 1} \log \mathbb{E}_t \left[ \mathbb{E}_t \left[ \exp \left\{ \frac{\epsilon - 1}{\epsilon} \log x_{it} \right\} | \tilde{\theta}_{it-1}, \lambda_{it} \right] \right] \\
&= \frac{\epsilon}{\epsilon - 1} \log \mathbb{E}_t \left[ \exp \left\{ \frac{\epsilon - 1}{\epsilon} \delta_t(e_k, \tilde{\theta}_{it-1}) + \frac{1}{2} \left( \frac{\epsilon - 1}{\epsilon} \right)^2 \sigma^2 \right\} \right] \\
&= \frac{\epsilon}{\epsilon - 1} \log \left( \int \sum_k \tilde{Q}_{t,k|\tilde{\theta}} \exp \left\{ \frac{\epsilon - 1}{\epsilon} \delta_t(e_k, \tilde{\theta}) + \frac{1}{2} \left( \frac{\epsilon - 1}{\epsilon} \right)^2 \sigma^2 \right\} dF_{\tilde{\theta}}(\tilde{\theta}) \right) \quad (179) \\
&= \delta_t(e_1, 1) + \frac{1}{2} \frac{\epsilon - 1}{\epsilon} \sigma^2 \\
& \quad + \frac{\epsilon}{\epsilon - 1} \log \left( \int \sum_k \tilde{Q}_{t,k|\tilde{\theta}} \exp \left\{ \frac{\epsilon - 1}{\epsilon} \left( \delta_t(e_k, \tilde{\theta}) - \delta_t(e_1, 1) \right) \right\} dF_{\tilde{\theta}}(\tilde{\theta}) \right)
\end{align*}
\]

Again, \( \hat{\sigma}^2 \) is a constant and \( \delta_t(e_1, 0) \) depends linearly on \( \log \theta_t \) and \( \log \theta_{t-1} \) and \( \delta_t(e_k, \tilde{\theta}) - \delta_t(e_1, 1) \) does not depend on \( \log \theta_t \) for all \( k \leq K \). Thus, we may write it as \( \delta_k \left( \theta_{t-1}, \tilde{\theta} \right) \).

Again, \( a_1 \) is the same as in Proposition 1. By the same steps as in Proposition 13, we then have that:

\[
f(\tilde{Q}, \theta_{t-1}) = \frac{\epsilon - 1}{\epsilon - 1 - \frac{\epsilon - 1}{\epsilon} \gamma} \log \left( \int \sum_k \tilde{Q}_{t,k|\tilde{\theta}} \exp \left\{ \frac{\epsilon - 1}{\epsilon} \delta_{k1} \left( \theta_{t-1}, \tilde{\theta} \right) \right\} dF_{\tilde{\theta}}(\tilde{\theta}) \right) \quad (180)
\]

Completing the proof. \( \square \)

We can use this result to study the additional effects induced by persistent idiosyncratic fundamentals. To do this, we restrict to the case of our main analysis with optimism and pessimism. In this context, we have that:

\[
f(Q) = \frac{\epsilon - 1}{\epsilon - 1 - \omega} \log \left( \mathbb{E}_{\tilde{\theta}} \left[ Q_{t|\tilde{\theta}} \exp \left\{ \frac{\epsilon - 1}{\epsilon} \delta_{OP}(\tilde{\theta}) \right\} + (1 - Q_{t|\tilde{\theta}}) \exp \left\{ \frac{\epsilon - 1}{\epsilon} \delta_{PP}(\tilde{\theta}) \right\} \right] \right) \quad (181)
\]

where:

\[
\begin{align*}
\delta_{OP}(\tilde{\theta}) &= \alpha \delta_{OP} + \frac{1 + \psi}{\alpha} + \frac{1}{\epsilon} \rho_{\tilde{\theta}} \log \tilde{\theta} \\
\delta_{PP}(\tilde{\theta}) &= \frac{1 + \psi}{\alpha} + \frac{1}{\epsilon} \rho_{\tilde{\theta}} \log \tilde{\theta}
\end{align*}
\]

(182)
We define $\xi = \frac{1+\psi}{\alpha + \psi} \rho \tilde{\theta}$ and observe that we can write:

$$\tilde{Q}_{t|\tilde{\theta}} \exp \left\{ \frac{\epsilon - 1}{\epsilon} \delta_{OP}(\tilde{\theta}) \right\} + (1 - \tilde{Q}_{t|\tilde{\theta}}) \exp \left\{ \frac{\epsilon - 1}{\epsilon} \delta_{PP}(\tilde{\theta}) \right\}$$

$$= Q_{t|\tilde{\theta}} \exp \left\{ \frac{\epsilon - 1}{\epsilon} \left( \alpha \delta_{OP} + \xi \log \tilde{\theta} \right) \right\} + (1 - Q_{t|\tilde{\theta}}) \exp \left\{ \frac{\epsilon - 1}{\epsilon} \xi \log \tilde{\theta} \right\}$$

Taking the expectation of the relevant terms, we obtain:

$$\mathbb{E}_{\tilde{\theta}} \left[ \tilde{Q}_{t|\tilde{\theta}} \exp \left\{ \frac{\epsilon - 1}{\epsilon} \delta_{OP}(\tilde{\theta}) \right\} + (1 - \tilde{Q}_{t|\tilde{\theta}}) \exp \left\{ \frac{\epsilon - 1}{\epsilon} \delta_{PP}(\tilde{\theta}) \right\} \right]$$

$$= \left[ \exp \left\{ \frac{\epsilon - 1}{\epsilon} \alpha \delta_{OP} \right\} - 1 \right] \exp \left\{ \frac{1}{2} \left( \frac{\epsilon - 1}{\epsilon} \xi \right)^2 \frac{\sigma^2_{\xi}}{1 - \rho^2_{\tilde{\theta}}} \right\} Q_t$$

$$+ \text{Cov}_t \left( Q_{t|\tilde{\theta}}, \tilde{\theta}^{t-1} \right) + \exp \left\{ \frac{1}{2} \left( \frac{\epsilon - 1}{\epsilon} \xi \right)^2 \frac{\sigma^2_{\xi}}{1 - \rho^2_{\tilde{\theta}}} \right\} \right) \right]$$

Thus, we have that the contribution of optimism to output is given by:

$$f(Q_t) = \frac{\epsilon - 1}{1 - \omega} \log \left( \left[ \exp \left\{ \frac{\epsilon - 1}{\epsilon} \alpha \delta_{OP} \right\} - 1 \right] \exp \left\{ \frac{1}{2} \left( \frac{\epsilon - 1}{\epsilon} \xi \right)^2 \frac{\sigma^2_{\xi}}{1 - \rho^2_{\tilde{\theta}}} \right\} Q_t$$

$$+ \text{Cov}_t \left( Q_{t|\tilde{\theta}}, \tilde{\theta}^{t-1} \right) + \exp \left\{ \frac{1}{2} \left( \frac{\epsilon - 1}{\epsilon} \xi \right)^2 \frac{\sigma^2_{\xi}}{1 - \rho^2_{\tilde{\theta}}} \right\} \right)$$

We observe that the first term is almost identical to that in our main analysis. This term is now intermediated by the effect of heterogeneity in previous productivity (to see this, observe that this vanishes when $\rho = 0$). Second, there is a new effect stemming from the covariance of optimism and productivity. Intuitively, when more optimistic firms are also more productive, they increase their production by more and this increases output. Finally, there is a level effect of heterogeneous productivity.

Thus, the sole new qualitative force is the covariance effect. To the extent that this does not vary with time, it can have no effect on dynamics. We investigate this in the data by estimating the regression model

$$\log \hat{\theta}_{it} = \sum_{\tau=1995}^{2019} \beta_{\tau} \cdot (\text{opt}_{i\tau} \cdot \mathbb{I}[\tau = t]) + \chi_{j(i),t} + \gamma_i + \varepsilon_{it}$$
where \((\chi_{ji}(i), t, \gamma_i)\) are industry-by-time and firm fixed effects, and \(\beta_s\) measures the (within-industry, within-firm) difference in mean log TFP for optimistic and pessimistic firms in each year. If the \(\beta_s\) vary systematically with the business cycle, then the shifting productivity composition of optimists over the business cycle is an important component of business-cycle dynamics.

We plot our coefficient estimates \(\beta_{\tau}\) in Figure A15. The estimates are generally positive, but economically small relative to the large observed variation in TFP, \(\log \theta_{it}\), which has an in-sample standard deviation of 0.84. Outside of the first two years and last year of the sample, we find limited evidence of time variation. Moreover, the variation that exists is not obviously correlated with the business cycle. This suggests that the compositional effect for optimists driven by narrative updating in response to idiosyncratic conditions is not, at least in our data, quantitatively significant.

B.7 Contrarianism, Endogenous Cycles, and Chaos

The baseline model can generate neither endogenous cycles nor chaotic dynamics without extrinsic shocks to fundamentals (as made formal by Lemma 1). This is because the probability that agents become optimistic is always increasing in the fraction of optimists in equilibrium.

In this appendix, we relax this assumption and delineate precise, testable conditions under which cyclical and chaotic dynamics occur in the absence of fundamental and aggregate shocks. We do so in a model with “contrarian” agents whose updating contradicts recent data and/or consensus. Our analysis of endogenous narratives with contrarianism therefore complements the literature on endogenous cycles in macroeconomic models (see, e.g., Boldrin and Woodford, 1990; Beaudry, Galizia, and Portier, 2020) by providing a further potential micro-foundation for the existence of endogenous cycles.

We begin by defining cycles and chaos. There exists a cycle of period \(k \in \mathbb{N}\) if \(Q = T^k(Q)\) and all elements of \(\{Q, T(Q), \ldots, T^{k-1}(Q)\}\) are non-equal. We will say that there are chaotic dynamics if there exists an uncountable set of points \(S \subset [0, 1]\) such that (i) for every \(Q, Q' \in S\) such that \(Q \neq Q'\), we have that \(\limsup_{t \to \infty} |T^t(Q) - T^t(Q')| > 0\) and \(\liminf_{t \to \infty} |T^t(Q) - T^t(Q')| = 0\) and (ii) for every \(Q \in S\) and periodic point \(Q' \in [0, 1]\), \(\limsup_{t \to \infty} |T^t(Q) - T^t(Q')| > 0\). This definition of chaos is due to Li and Yorke (1975) and can be understood as saying that there is a large set of points such that the iterated dynamics starting from any two points in this set get both far apart and vanishingly close.
A Variant Model with the Potential for Cycles and Chaos. We will study the issue of cycles and chaos under the simplifying assumption that, in equilibrium, the induced probabilities that optimists and pessimists respectively become optimists are quadratic and given by:

\[ \tilde{P}_O(Q) = a_O + b_O Q - c Q^2, \quad \tilde{P}_P(Q) = a_P + b_P Q - c Q^2 \] (187)

with parameters \((a_O, a_P, b_O, b_P, c) \in \mathbb{R}^5\) such that \(P_O([0, 1]), P_P([0, 1]) \subseteq [0, 1]\). The parameters \(a_O\) and \(a_P\) index stubbornness, \(b_O\) and \(b_P\) capture both contagiousness and associativeness (through the subsumed equilibrium map), and \(c\) captures any non-linearity.

The following result describes the potential dynamics:

**Proposition 15.** The following statements are true:

1. When \(\tilde{P}_O \geq \tilde{P}_P\) and both are monotone, there are neither cycles of any period nor chaotic dynamics.
2. When \(\tilde{P}_O\) and \(\tilde{P}_P\) are linear, cycles of period 2 are possible, cycles of any period \(k > 2\) are not possible, and chaotic dynamics are not possible.
3. Without further restrictions on \(\tilde{P}_O\) and \(\tilde{P}_P\), cycles of any period \(k \in \mathbb{N}\) and chaotic dynamics are possible.

**Proof.** The dynamics of optimism are characterized by the transition map

\[ T(Q) = Q(a_O + b_O Q - c Q^2) + (1 - Q)(a_P + b_P Q - c Q^2) \]

\[ = a_P + (a_O - a_P + b_P)Q - (c + b_P - b_O) Q^2 \] (188)

where we define \(\omega_0 = a_P, \omega_1 = (a_O - a_P + b_P), \omega_2 = (c + b_P - b_O)\) for simplicity. We first show that the dynamics described by \(T\) are topologically conjugate to those of the logistic map \(\tilde{T}(x) = \eta x (1 - x)\) with

\[ \eta = 1 + \sqrt{(a_O - a_P + b_P - 1)^2 + 4a_P(c + b_P - b_O)} \] (189)

Two maps \(T : [0, 1] \to [0, 1]\) and \(T' : [0, 1] \to [0, 1]\) are topologically conjugate if there exists a continuous, invertible function \(h : [0, 1] \to [0, 1]\) such that \(T' \circ h = h \circ T\). If \(T\) is

39This simplifying assumption is without any qualitative loss as this model can demonstrate the full range of potential cyclical and chaotic dynamics.

40This can be microfounded in a generalization our earlier LAC model by taking \(P_i(\log Y, Q) = u_i + r_i \log Y + s_i Q - c Q^2\) for \(i \in \{O, P\}\) and approximating \(f(Q) \approx \frac{\alpha \delta^{OP}}{1 - \omega} Q\). In this case:

\[ \tilde{P}_i(Q) = (u_i + r_i a_0 + r_i a_1 \log \theta) + \left( r_i \frac{\alpha \delta^{OP}}{1 - \omega} + s_i \right) Q - c Q^2 \]
topologically conjugate to \( T' \) and we know the orbit of \( T' \), we can compute the orbit of \( T \) via the formula:

\[
T^k(Q) = \left( h^{-1} \circ T'^k \circ h \right)(Q) \tag{190}
\]

Hence, we can prove the properties of interest using known properties of the map \( 	ilde{T} \) as well as the mapping from the deeper parameters of \( T \) to the parameters of \( \tilde{T} \).

To show the topological conjugacy of \( T \) and \( \tilde{T} \), we proceed in three steps:

1. \( T \) is topically topologically conjugate to the quadratic map \( \hat{T}(Q) = Q^2 + k \) for appropriate choice of \( k \). We guess the following homeomorphism \( \hat{h}(Q) = \hat{\alpha} + \hat{\beta}Q \). Plugging \( \hat{h} \) in \( \hat{T} \), we have that:

\[
\hat{T}(\hat{h}(Q)) = (k + \hat{\alpha}^2) + 2\hat{\alpha}\hat{\beta}Q + \hat{\beta}^2Q^2 \tag{191}
\]

Inverting \( \hat{h} \) and applying it to this expression yields:

\[
\hat{h}^{-1}(\hat{T}(\hat{h}(Q))) = \frac{k + \hat{\alpha}(\hat{\alpha} - 1)}{\hat{\beta}} + 2\hat{\alpha}Q + \hat{\beta}Q^2 \tag{192}
\]

To verify topological conjugacy, we need to show that \( T(Q) = \hat{h}^{-1}(\hat{T}(\hat{h}(Q))) \). Matching coefficients, this is the case if and only if:

\[
\omega_0 = \frac{k + \hat{\alpha}(\hat{\alpha} - 1)}{\hat{\beta}}, \quad \omega_1 = 2\hat{\alpha}, \quad \omega_2 = -\hat{\beta} \tag{193}
\]

We therefore have that:

\[
k = \hat{\beta}\omega_0 + \hat{\alpha}(1 - \hat{\alpha}) = -\omega_2\omega_0 + \frac{\omega_1}{2} \left( 1 - \frac{\omega_1}{2} \right) \tag{194}
\]

with \( \hat{h}(Q) = \frac{\omega_1}{2} - \omega_2Q \).

2. \( \hat{T} \) is topologically conjugate to \( \tilde{T} \) for appropriate choice of \( \eta \). We guess the following homeomorphism \( \tilde{h}(Q) = \tilde{\alpha} + \tilde{\beta}Q \). Plugging \( \tilde{h} \) in \( \tilde{T} \), we obtain:

\[
\tilde{T}(\tilde{h}(Q)) = \eta (\tilde{\alpha}(1 - \tilde{\alpha}) + \tilde{\beta}(1 - 2\tilde{\alpha})Q - \tilde{\beta}^2Q^2) \tag{195}
\]

Inverting \( \tilde{h} \) and applying it, we obtain:

\[
\tilde{h}^{-1}(\tilde{T}(\tilde{h}(Q))) = \frac{\eta\tilde{\alpha}(1 - \tilde{\alpha}) - \tilde{\alpha}}{\tilde{\beta}} + \eta(1 - 2\tilde{\alpha})Q - \eta\tilde{\beta}Q^2 \tag{196}
\]
Matching coefficients, we find:

\[ k = \frac{\eta \tilde{\alpha}(1 - \tilde{\alpha}) - \tilde{\alpha}}{\tilde{\beta}}, \quad 0 = \eta(1 - 2\tilde{\alpha}), \quad 1 = -\eta \tilde{\beta} \]  

(197)

We therefore obtain that:

\[ k = \eta(\tilde{\alpha} - \eta(1 - \tilde{\alpha})) = \frac{\eta}{2} \left(1 - \frac{\eta}{2}\right) \]  

(198)

which implies that \( \eta = 1 + \sqrt{1 - 4k} \) with \( \tilde{h}(Q) = \frac{1}{2} - \frac{1}{1 + \sqrt{1 - 4k}}Q \).

3. \( T \) is topologically conjugate to \( \tilde{T} \) for appropriate choice of \( \eta \). We now compose the mappings proved in steps 1 and 2 to show

\[ T = \tilde{h}^{-1} \circ \tilde{h}^{-1} \circ \tilde{T} \circ \tilde{h} \circ \tilde{h} \]  

(199)

with

\[ \eta = 1 + \sqrt{1 - 4 \left(-\omega_2 \omega_0 + \frac{\omega_1}{2} \left(1 - \frac{\omega_1}{2}\right)\right)} = 1 + \sqrt{(\omega_1 - 1)^2 + 4\omega_2 \omega_0} \]  

(200)

and therefore that \( T \) is topologically conjugate to \( \tilde{T} \).

Having shown the conjugacy of \( T \) to \( \tilde{T} \), we now find bounds on \( \eta \) implied by each case and use this conjugacy to derive the implications for possible dynamics. The following points prove each claim 1-3 in the original Proposition.

1. \( \tilde{P}_O \geq \tilde{P}_P \) and both are monotone. Thus, \( T \) is increasing and there cannot be cycles or chaos. This implies that \( \eta < 3 \) (see Weisstein, 2001, for reference).

2. \( \tilde{P}_O \) and \( \tilde{P}_P \) are linear. It suffices to show that we can attain \( \eta > 3 \) but that \( \eta \) must be less than \( 1 + \sqrt{6} \) (see Weisstein, 2001, for reference). In this case, \( c = 0 \). This is in addition to the requirements that \( \max_{Q \in [0,1]} \tilde{P}_i(Q) \leq 1 \) and \( \min_{Q \in [0,1]} \tilde{P}_i(Q) \geq 0 \) for \( i \in \{O, P\} \), which can be expressed as:

\[
\begin{align*}
\max_{Q \in [0,1]} \tilde{P}_i(Q) &= \max \left\{ a_i, a_i + b_i - c, \left(a_i + \frac{b_i^2}{4c}\right) I_0 \leq b_i \leq 2c \right\} \leq 1 \\
\min_{Q \in [0,1]} \tilde{P}_i(Q) &= \min \{a_i, a_i + b_i - c\} \geq 0
\end{align*}
\]  

(201)

The maximal value of \( \eta \) consistent with these restrictions can therefore be obtained by
solving the following program:

\[
\max_{(a_O,a_P,b_O,b_P) \in \mathbb{R}^4} (a_O - a_P + b_P - 1)^2 + 4a_P(b_P - b_O)
\]
\[
\text{s.t. } \max \{a_O, a_O + b_O\} \leq 1, \max \{a_P, a_P + b_P\} \leq 1
\]
\[
\min \{a_O, a_O + b_O\} \geq 0, \min \{a_P, a_P + b_P\} \geq 0
\]

Exact solution of this program via Mathematica yields that the maximum value is 5. This implies that the maximum value of \(\eta\) is \(1 + \sqrt{5} \approx 3.23\), which is greater than 3 but less than \(1 + \sqrt{6}\). Moreover, this maximum is attained at \(a_O = 0, a_P = 1, b_O = 0, b_P = -1\).

3. No further restrictions on \(\tilde{P}_O\) and \(\tilde{P}_P\). We can attain \(\eta = 4\) by setting \(a_0 = a_P = 0, b_O = b_P = 4, c = 4\). Thus, cycles of any period \(k \in \mathbb{N}\) and chaotic dynamics can occur (see Weisstein, 2001, for reference).

\[\square\]

The proof of this result follows a classic approach of recasting a quadratic difference equation as a logistic difference equation via topological conjugacy (see, e.g., Battaglini, 2021; Deng, Khan, and Mitra, 2022). The restrictions on structural parameters implied by the hypotheses of the proposition then yield upper bounds on the possible logistic maps and allow us to characterize the possible dynamics using known results.

To understand this result, observe in our baseline case in which \(T\) is monotone that cycles and chaos are not possible. This is because there is no potential for optimism to sufficiently overshoot its steady state. By contrast, when \(\tilde{P}_O\) and \(\tilde{P}_P\) are either non-monotone or non-ranked, two-period cycles can take place where the economy undergoes endogenous boom-bust cycles with periods of high optimism and high output ushering in periods of low optimism and low output (and vice versa) as contrarians switch positions and consistently overshoot the (unstable) steady state. Finally, when \(\tilde{P}_O\) and \(\tilde{P}_P\) are non-linear and non-monotone, essentially any richness of dynamics can be achieved via erratic movements in optimism that are extremely sensitive to initial conditions.

**An Empirical Test for Cycles and Chaos.** Proposition 15 shows how to translate an updating rule of the form of Equation 187 into predictions about the potential for cycles and chaos. We now estimate this updating rule in the data to test these predictions empirically. Concretely, in our panel dataset of firms, we estimate the regression model

\[
\text{opt}_{i,t} = \alpha_1 \text{opt}_{i,t-1} + \beta_1 \text{opt}_{i,t-1} \cdot \text{opt}_{i,t-1} + \\
\beta_2 (1 - \text{opt}_{i,t-1}) \cdot \text{opt}_{i,t-1} + \tau (\text{opt}_{i,t-1})^2 + \gamma_i + \varepsilon_{it}
\]
where $\gamma_i$ is a firm fixed effect. This model allows the effects of contagiousness to depend on agents’ previous state. In the mapping to Equation 187, $\alpha = a_P$, $\alpha_1 = a_O - a_P$, $\beta_1 = b_O$, $\beta_2 = b_P$, and $\tau = c$. With estimates of each regression parameter, denoted by a hat, we also obtain an estimate of the logistic map parameter $\eta$ defined in Equation 189:

$$
\hat{\eta} = 1 + \sqrt{\hat{\alpha}_1 + \hat{\beta}_2 - 1}^2 + 4\hat{\alpha}_1(\hat{\tau} + \hat{\beta}_2 - \hat{\beta}_1)
$$

Since $\hat{\eta}$ is a nonlinear function of estimated parameters in the regression, we can conduct inference on $\hat{\eta}$ using the delta method. Moreover, this constitutes a test for the possibility of cycles and chaos in the model by the logic of Proposition 15. Specifically, as described in the proof of that result, there are two main cases. First, if $\eta < 3$, then case 1 of the result obtains: there are neither cycles of any period nor chaotic dynamics. Second, if $\eta \geq 3$, there can be cycles of period 2 or more and/or chaos. Moreover, if $\eta > 3.57$, chaotic dynamics obtain.

Our estimates are presented in Table A20. Our point estimate of $\eta$ is 1.443 and the 95% confidence interval is (0.076, 2.810). This rules out, at the 5% level, the presence of cycles and/or chaos. The 99% confidence interval is (−0.354, 3.240), which does not rule out cycles. The $p$-value for the chaotic dynamics threshold is 0.001. Thus, our results provide strong evidence against the possibility of chaos due to contagious optimism, and marginally weaker evidence against the possibility of cycles. This test complements the literature on endogenous cycles in macroeconomic models (see, e.g., Boldrin and Woodford, 1990; Beaudry, Galizia, and Portier, 2020) by providing a micro-founded test within a structural economic model, which may ameliorate challenges associated with interpreting pure time-series evidence (see, e.g., Werning, 2017).

### B.8 Narratives in Games and the Role of Higher-Order Beliefs

We have studied a micro-founded business-cycle model, but the basic insights extend much more generally to abstract, linear beauty contest games. Importantly, these settings provide us with an ability to disentangle the dual roles of narratives in affecting both agents’ first-order and higher-order beliefs about fundamentals.

Concretely, suppose that agents’ best replies are given by the following beauty contest form (see, e.g., Morris and Shin, 2002):

$$
x_{it} = \alpha E_t[\theta_i] + \beta E_t[Y_i]
$$

where $\alpha > 0$ and $\beta \in [0, 1)$. This linear form for best replies is commonly justified by (log-
linearization of some underlying best response function (see, e.g., Angeletos and Pavan, 2007). For example, log-linearization of the agents’ best replies in the baseline model of this section yields such an equation with \( \beta = \omega \) and all variables above standing in for their log-counterparts. Moreover, suppose that aggregation is linear so that \( Y_t = \int_{[0,1]} x_{it} di \). This can similarly be justified via an appropriate first-order expansion of non-linear aggregators. Finally, we let the structure of narratives be as before.

Toward characterizing equilibrium, we define the average expectations operator:

\[
\overline{E}_t[\theta_t] = \int_{[0,1]} E_{it} [\theta_t] di
\]  

and the higher-order average expectations operator for \( k \in \mathbb{N} \) as:

\[
\overline{E}_t^k[\theta_t] = \int_{[0,1]} E_{it} \left[ \overline{E}_t^{k-1}[\theta_t] \right] di
\]  

Moreover, we observe by recursive substitution that equilibrium aggregate output is given by:

\[
Y_t = \alpha \sum_{k=1}^{\infty} \beta^{k-1} \overline{E}_t^k[\theta_t]
\]  

We can therefore solve for the unique equilibrium by computing the hierarchy of higher-order expectations. We can do this in closed-form by observing that agents’ idiosyncratic first-order beliefs are given by:

\[
E_{it}[\theta_t | s_{it}, \lambda_{it}] = \kappa s_{it} + (1 - \kappa) \left( \lambda_{it} \mu_O + (1 - \lambda_{it}) \mu_P \right)
\]  

which allows us to compute average first-order expectations of fundamentals as:

\[
\overline{E}_t[\theta_t] = \kappa \theta_t + (1 - \kappa) (Q_t \mu_O + (1 - Q_t) \mu_P)
\]  

which is a weighted average between true fundamentals and the average impact of narratives on agents’ priors. By taking agents’ expectations over this object and averaging, we compute higher-order average expectations as:

\[
\overline{E}_t^k[\theta_t] = \kappa^k \theta_t + (1 - \kappa^k) (Q_t \mu_O + (1 - Q_t) \mu_P)
\]  

which is again a weighted average between the state and agents’ priors, but now with a geometrically increasing weight on narratives as we consider higher-order average beliefs.

The following result characterizes aggregate output and agents’ best replies in the unique
Proposition 16 (Narratives and Higher-Order Beliefs). There exists a unique equilibrium. In this unique equilibrium, aggregate output is given by:

\[ Y_t = \frac{\alpha}{1-\beta} \left( \frac{(1-\beta)\kappa}{1-\beta\kappa} \theta_t + \frac{1-\kappa}{1-\beta\kappa} (Q_t\mu_O + (1-Q_t)\mu_P) \right) \]  \hspace{1cm} (212)

Moreover, agents’ actions follow:

\[ x_{it} = \alpha \frac{1}{1-\beta\kappa} [\kappa\theta_t + \kappa\epsilon_{it} + (1-\kappa) (\lambda_{it}\mu_O + (1-\lambda_{it})\mu_P)] \]
\[ + \beta \frac{\alpha}{1-\beta} \frac{1-\kappa}{1-\beta\kappa} (Q_t\mu_O + (1-Q_t)\mu_P) \]  \hspace{1cm} (213)

Proof. To substantiate the arguments in the main text, by aggregating Equation 205, we obtain that:

\[ Y_t = \alpha \mathbb{E}_t[\theta_t] + \beta \mathbb{E}_t[Y_t] \]  \hspace{1cm} (214)

Thus, by recursive substitution \( k \) times we obtain that:

\[ Y_t = \alpha \sum_{j=1}^{k} \beta^{j-1} \mathbb{E}_t^j[\theta_t] + \beta^k \mathbb{E}_t^k[Y_t] \]  \hspace{1cm} (215)

Moreover, we have that:

\[ \mathbb{E}_t^j[\theta_t] = \kappa^j\theta_t + (1-\kappa^j)(Q_t\mu_O + (1-Q_t)\mu_P) \]  \hspace{1cm} (216)

and thus that:

\[ \alpha \sum_{j=1}^{k} \beta^{j-1} \mathbb{E}_t^j[\theta_t] = \alpha \sum_{j=1}^{k} \beta^{j-1} (\kappa^j\theta_t + (1-\kappa^j)(Q_t\mu_O + (1-Q_t)\mu_P)) \]
\[ = \alpha \sum_{j=1}^{k} \beta^{j-1} (Q_t\mu_O + (1-Q_t)\mu_P) + \alpha \beta^{-1} \sum_{j=1}^{k} (\beta\kappa)^j [\theta_t - (Q_t\mu_O + (1-Q_t)\mu_P)] \]  \hspace{1cm} (217)

Hence:

\[ \lim_{k \to \infty} \alpha \sum_{j=1}^{k} \beta^{j-1} \mathbb{E}_t^j[\theta_t] = \frac{\alpha}{1-\beta} (Q_t\mu_O + (1-Q_t)\mu_P) + \frac{\alpha\kappa}{1-\beta\kappa} [\theta_t - (Q_t\mu_O + (1-Q_t)\mu_P)] \]  \hspace{1cm} (218)
We therefore have that there is a unique equilibrium if \( \lim_{k \to \infty} \beta^k E_t^k[Y_t] = 0 \). Hellwig and Veldkamp (2009) show in Proposition 1 of their supplementary material that all equilibria differ on a most a measure zero set of fundamentals. In this setting, this implies that \( \lim_{k \to \infty} \beta^k E_t^k[Y_t] = c \) for some \( c \in \mathbb{R} \) for almost all \( \theta \in \Theta \). Hence, the equilibrium is given by:

\[
Y_t = \frac{\alpha}{1 - \beta} (Q_t \mu_O + (1 - Q_t) \mu_P) + \frac{\alpha \kappa}{1 - \beta \kappa} \left[ \theta_t - (Q_t \mu_O + (1 - Q_t) \mu_P) \right] + c
\]

\( \begin{align*}
&= \frac{\alpha}{1 - \beta} \left( (1 - \beta) \kappa \theta_t + \frac{1 - \kappa}{1 - \beta \kappa} (Q_t \mu_O + (1 - Q_t) \mu_P) \right) + c \\
&= \frac{\alpha}{1 - \beta} \left( (1 - \beta) \kappa \theta_t + \frac{1 - \kappa}{1 - \beta \kappa} (Q_t \mu_O + (1 - Q_t) \mu_P) \right) + c
\end{align*} \) (219)

But then we have that \( c = 0 \) by computing \( \lim_{k \to \infty} \beta^k E_t^k[Y_t] = 0 \) under this equilibrium.

Finally, to solve for individual actions under this equilibrium, we compute:

\[
x_{it} = \alpha E_t[\theta_t] + \beta E_t[Y_t] \\
= \alpha E_t[\theta_t] + \beta E_t \left[ \frac{\alpha}{1 - \beta} \left( (1 - \beta) \kappa \theta_t + \frac{1 - \kappa}{1 - \beta \kappa} (Q_t \mu_O + (1 - Q_t) \mu_P) \right) \right] \\
= \left( \alpha + \beta \frac{\alpha}{1 - \beta} \frac{(1 - \beta) \kappa}{1 - \beta \kappa} \right) E_t[\theta_t] + \beta \frac{\alpha}{1 - \beta \kappa} \left( Q_t \mu_O + (1 - Q_t) \mu_P \right) \\
= \frac{\alpha}{1 - \beta \kappa} \left( \kappa s_{it} + (1 - \kappa) (\lambda_{it} \mu_O + (1 - \lambda_{it}) \mu_P) \right) \\
+ \beta \frac{\alpha}{1 - \beta \kappa} \left( Q_t \mu_O + (1 - Q_t) \mu_P \right)
\]

Completing the proof. \( \square \)

This result allows us to see how narratives affect output by propagating up through the hierarchy of higher-order beliefs. Concretely, we have that the static impulse response of output to a contemporaneous shock to the fraction of optimists in the population is given by:

\[
\frac{\partial Y_t}{\partial Q_t} = \frac{\alpha}{1 - \beta} \frac{1 - \kappa}{1 - \beta \kappa} (\mu_O - \mu_P) = \alpha \sum_{j=1}^{\infty} \beta^{j-1} (1 - \kappa^j) (\mu_O - \mu_P)
\]

The first expression is composed of the relative importance of fundamentals \( \frac{\alpha}{1 - \beta} \), the impact of prior beliefs on the entire hierarchy of higher-order beliefs about exogenous and endogenous outcomes \( \frac{1 - \kappa}{1 - \beta \kappa} \), and the difference between the two narratives \( \mu_O - \mu_P \). The second expression re-expands the hierarchy of beliefs, to highlight how fraction

\[
\frac{\beta^{j-1} (1 - \kappa^j)}{\frac{1 - \kappa}{1 - \beta \kappa}}
\]

(222)
of the total effect is driven by beliefs of order \( j \). These weights decline more slowly if complementarity \( \beta \) or prior weights \( 1 - \kappa \) are high.

Finally, our result shows how the regression equation relating individual actions with narrative weights, estimated in our main analysis, holds in equilibrium in the linearized beauty contest. Thus, our empirical strategy is compatible with the interpretation that the macroeconomy is best described by a linear beauty contest, and moreover can be ported to other settings where this modeling assumption may be appropriate, such as that of financial speculation (see e.g., Allen, Morris, and Shin, 2006).

B.9 Model with Firm Dynamics

We now sketch an augmentation of our baseline conceptual model of the firm from which we derived our earlier estimating equations (see Appendix A.1) to allow for persistent idiosyncratic states and adjustment costs. This allows us to more formally justify why controlling for firm productivity and lagged labor is sufficient to account for the presence of adjustment costs to first-order.

In every period \( t \), each firm \( i \) still takes an action \( x_{it} \in \mathcal{X} \). Their objective function still takes as an input their action, aggregate outcomes \( Y_t \in \mathcal{Y} \), and aggregate fundamentals \( \theta_t \) (which in analogy to the previous appendix sections, we allow to follow a first-order (continuous) Markov process). However, they now have idiosyncratic fundamentals \( \tilde{\theta}_{it} \), which follow a first-order (continuous) Markov process. Moreover, their actions are subject to adjustment costs \( \Phi : \mathbb{R} \rightarrow \mathbb{R}_+ \) equal to \( \Phi(x - x_{-1}) \) when their last action was \( x_{-1} \). Thus, we let their flow utility be \( u(x, Y, \theta, \tilde{\theta}) - \Phi(x - x_{-1}) \). The firm discounts the future at rate \( \beta_i \in [0, 1) \). The aggregate state variables in period \( t \) are the distribution of \( x_{it-1} \) in the population \( F^x_{t-1} \), the distribution of narratives in the population \( Q_t \), and the level of current and past aggregate fundamentals \( \theta_t \) and \( \theta_{t-1} \). Thus, equilibrium aggregate output is described by some function \( \hat{Y}(F^x_{t-1}, Q_t, \theta_t, \theta_{t-1}) \). Moreover, observe at time \( t \) that the following are the state variables for a firm: (i) the level of idiosyncratic productivity in the previous period \( \tilde{\theta}_{it-1} \) (ii) the level of aggregate productivity in the previous period \( \theta_{t-1} \) (iii) the firm’s action in the previous period \( x_{it-1} \) (iv) the narrative entertained by the agent \( \lambda_{it} \) (v) their current signal about fundamentals \( s_{it} \), and (vi) the additional aggregate states \( (F^x_{t-1}, Q_t) \).

We can therefore represent any firm policy function as:

\[
x_{it} = g(x_{it-1}, \theta_{t-1}, \tilde{\theta}_{it-1}, F^x_{t-1}, Q_t, \lambda_{it}, s_{it})
\] (223)
If this is differentiable, we may linearize it to obtain:

\[ x_{it} \approx \gamma_i + \chi_t + \sum_{k=1}^{K} \delta_k \lambda_{k, it} + \gamma \theta_{it-1} + \omega x_{it-1} + \varepsilon_{it} \]  

(224)

where the aggregate fixed effect now absorbs \((F^x_{t-1}, Q_t, \theta_t, \theta_{t-1})\), \(\theta_{it-1}\) capture agents’ idiosyncratic expectations of future fundamentals, and \(x_{it-1}\) captures their adjustment costs.
C Additional Details on Textual Data

C.1 Obtaining and Processing 10-Ks

Here, we describe our methodology for obtaining and processing raw data on 10-K filings. We start with raw html files downloaded directly from the SEC’s EDGAR (Electronic Data Gathering, Analysis, and Retrieval) system. Each of these files corresponds to a single 10-K filing. Each file is identified by its unique accession number. In its heading, each file also contains the end-date for the period the report concerns (e.g., 12/31/2018 for a FY 2018 ending in December), and a CIK (Central Index Key) firm identifier from the SEC. We use standard linking software provided by Wharton Research Data Services (WRDS) to link CIK numbers and fiscal years to the alternative firm identifiers used in data on firm fundamentals and stock prices. We have, in our original dataset, 182,259 files.

We follow the following steps to turn each document, now identified by firm and year, into a bag-of-words representation:

1. *Cleaning raw text.* We first translate the document into unformatted text. Specifically, we follow the following steps in order:
   
   (a) Removing hyperlinks and other web addresses
   (b) Removing html formatting tags encased in the brackets <>
   (c) Making all text lowercase
   (d) Removing extra spaces, tabs, and new lines.
   (e) Removing punctuation
   (f) Removing non-alphabetical characters

2. *Removing stop words.* Following standard practice, we remove “stop words” which are common in English but do not convey specific meaning in our analysis. We use the default English stop word list in the nltk Python package. Example stopwords include articles (“a”, “the”), pronouns (“I”, “my”), prepositions (“in”, “on”), and conjunctions (“and”, “while”).

3. *Lemmatizing documents.* Again following standard practice, we use lemmatization software to reduce words to their common roots. We use the default English-language lemmatizer of the spacy Python package. The lemmatizer uses both the word’s identity and its content to transform sentences. For instance, when each is used as a verb, “meet,” “met,” and “meeting” are commonly lemmatized to “meet.” But if the software predicts that “meeting” is used as a noun, it will be lemmatized as the noun “meeting.”
4. *Estimating a bigram model.* We estimate a bigram model to group together commonly co-occurring words as single two-word phrases. We use the `phrases` function of the `gensim` package. The bigram modeler groups together words that are almost always used together. For instance, if our original text data set were the 10-Ks of public firms Nestlé and General Mills, the model may determine that “ice” and “cream,” which almost always appear together, are part of a bigram “ice_cream.”

5. *Computing the bag of words representation.* Having now expressed each document as a vector of clean words (*i.e.*, single words and bigrams), we simply collapse these data to frequencies.

Finally, note that our procedure uses *all* of the non-formatting text in the 10K. This includes all sections of the documents, and does not limit to the Management Discussion and Analysis (MD&A) section. This is motivated by the fact that management’s discussion is not limited to one section SEC (2011). Moreover, prior literature has found that textual analysis of the entire 10-K versus the MD&A section tends to closely agree, and that limiting scope to the MD&A section has limited practical benefits due to the trade-off of limiting the amount of text per document (Loughran and McDonald, 2011).

C.2 Obtaining and Processing Conference Call Text

We obtain the full text of sales and earnings conference calls from 2002 to 2014 from the Fair Disclosure (FD) Wire service. The original sample includes 261,034 documents, formatted as raw text. We next subset to documents that have reported firm names and stock tickers, which are automatically associated with documents by Lexis Nexis. When matches are probabilistic, we use the first (highest probability) match. We finally restrict to firms that are listed on one of three US stock exchanges: the NYSE, the NASDAQ, or the NYSE-MKT (Small Cap). We finally connect tickers to the firm identifiers in our fundamentals data using the master cross-walk available on Wharton Research Data Services (WRDS). These operations together reduce the sample size to 158,810 calls. We clean these data by conducting steps 1-3 described above in Appendix C.1. We then calculate positive word counts, negative word counts, and optimism exactly as described in the main text for the 10-K data.

C.3 Measuring Positive and Negative Words

To calculate sets of positive and negative 10K words, we use the updated dictionary available online at McDonald (2021) as of June 2020. This dictionary includes substantial updates

\[^{41}\text{In the essentially zero-measure cases in which there is a tie, we take the alphabetically first ticker.}\]
relative to the dictionaries associated with the original Loughran and McDonald (2011) publication. These changes are reviewed in the Documentation available at McDonald (2021).

The Loughran-McDonald dictionary includes 2345 negative words and 347 positive words. The dictionary is constructed to include multiple forms of each relevant word. For instance, the first negative root “abandon” is listed as: “abandon,” “abandoned,” “abandoning,” “abandonment,” “abandonments,” and “abandons.” To ensure consistency with our own lemmatization procedure, we first map each unique word to all of its possible lemmas using the getAllLemmas function of the lemminflect Python package, which is an extension to the spacy package we use for lemmatization. We then construct a new list of negative words by combining the original list of negative words with all new, unique lemmas to which a negative word mapped (and similarly for positive words). This procedure results in new lists of 2411 negative words and 366 positive words, which map exactly to the words that appear in our cleaned bag of words representation. We list the top ten most common positive and negative words from this cleaned set in Table A1. In particular, to make the table most legible, we first associate words with their lemmas, then count the sum of document frequencies for each associated word (which may exceed one), and then print the most common word associated with the lemma.
D Additional Details on Firm Fundamentals Data

D.1 Compustat: Data Selection

Our data selection criteria and variable definitions are identical to those used in Flynn and Sastry (2022). In this Appendix, we review essential points. We refer the reader to the Appendix material of Flynn and Sastry (2022) for certain details.

Our dataset is Compustat Annual Fundamentals. Our main variables of interest are defined in Appendix Table A21. We restrict the sample to firms based in the United States, reporting statistics in US Dollars, and present in the “Industrial” dataset. We exclude firms whose 2-digit NAICS is 52 (Finance and Insurance) or 22 (Utilities). This filter eliminates firms in two industries that, respectively, may have highly non-standard production technology and non-standard market structure.

We summarize our definitions of major “input and output” variables in Appendix Table A21. For labor choice, we measure the number of employees. For materials expenditure, we measure the sum of reported variable costs (cogs) and sales and administrative expense (xsga) net of depreciation (dp).\footnote{As in Ottonello and Winberry (2020) and Flynn and Sastry (2022), we use a perpetual inventory method to calculate the value of the capital stock. We start with the first reported observation of gross value of plant, property, and equipment and add net investment or the differences in net value of plant, property, and equipment. Note that, because all subsequent analysis is conditional on industry-by-time fixed effects, it is redundant at this stage to deflate materials and capital expenditures by industry-specific deflators.}

\footnote{A small difference from Flynn and Sastry (2022) is that, in assessing the firms’ costs and later calculating TFP, we do not “unbundle” materials expenditures on labor and non-labor inputs using supplemental data on annual wages.}

We categorize the data into 44 sectors. These are defined at the 2-digit NAICS level, but for the Manufacturing (31-33) and Information (51) sectors, which we classify at the 3-digit level to achieve a better balance of sector size. More summary information about these industries is provided in Appendix F of Flynn and Sastry (2022).

D.2 Compustat: Calculation of TFP

When calculating firms’ Total Factor Productivity, we restrict attention to a subset of our sample that fulfils the following inclusion criteria:

1. Sales, material expenditures, and capital stock are strictly positive;
2. Employees exceed 10;
3. Acquisitions as a proportion of assets (aqc over at) does not exceed 0.05.

The first ensures that all companies meaningfully report all variables of interest for our production function estimation; the second applies a stricter cut-off to eliminate firms that are very small, and lead to outlier estimates of productivity and choices. The third is a simple screening device for large acquisitions which may spuriously show up as large innovations in firm choices and/or productivity.

Our method for recovering total factor productivity is based on cost shares. In brief, we use cost shares for materials and labor to back out production elasticities, and treat the elasticity of capital as the implied “residual” given an assumed mark-up $\mu > 1$ (in our baseline, $\mu = 4/3$) and constant physical returns-to-scale. The exact procedure is the following:

1. For all firms in industry $j$, calculate the estimated materials share:

$$\text{Share}_{M,j'} = \frac{\sum_{i:j(i)=j'} \sum_t \text{MaterialExpenditure}_{it}}{\sum_{i:j(i)=j'} \sum_t \text{Sales}_{it}} \quad (225)$$

2. If $\text{Share}_{M,j'} \leq \mu^{-1}$, then set

$$\alpha_{M,j'} = \mu \cdot \text{Share}_{M,j'}$$
$$\alpha_{K,j'} = 1 - \alpha_{M,j'} - \alpha_{L,j'} \quad (226)$$

3. Otherwise, adjust shares to match the assumed returns-to-scale, or set

$$\alpha_{M,j'} = 1$$
$$\alpha_{K,j'} = 0 \quad (227)$$

To translate our production function estimates into productivity, we calculate a “Sales Solow Residual” $\hat{\theta}_{it}$ of the following form:

$$\log \hat{\theta}_{it} = \log \text{Sales}_{it} - \frac{1}{\mu} \left( \alpha_{M,j(i)} \cdot \log \text{MatExp}_{it} + \alpha_{K,j(i)} \cdot \log \text{CapStock}_{it} \right) \quad (228)$$

We finally define our estimate $\log \hat{\theta}$ as the previous net of industry-by-time fixed effects

$$\log \hat{\theta}_{it} = \log \hat{\theta}_{it} - \chi_{j(i),t} \quad (229)$$

**Theoretical Interpretation.** The aforementioned method recovers physical productivity (“TFPQ”) under the assumptions, consistent with our quantitative model, that firms operate
constant returns-to-scale technology and face an isoleastic, downward-sloping demand curve of known elasticity (equivalently, they charge a known markup). The idea is that, given the known markup, we can impute firms’ (model-consistent) costs as a fixed fraction of sales and then calculate the theoretically desired cost shares. Here, we describe the simple mathematics.

There is a single firm $i$ operating in industry $j$ with technology

$$Y_i = \theta_i M_i^{\alpha_j} K_i^{1-\alpha_j} \quad (230)$$

They act as a monopolist facing the demand curve

$$p_i = Y_i^{\frac{1}{\epsilon}} \quad (231)$$

for some inverse elasticity $\epsilon > 1$. Observe that this is, up to scale, the demand function faced by monopolistically competitive intermediate goods producers in our model. The firm’s revenue is therefore $p_i Y_i = Y_i^{1 - \frac{1}{\epsilon}}$. Finally, the firm can buy materials at industry-specific price $q_j$ and rent capital at rate $r_j$. The firm’s program for profit maximization is therefore

$$\max_{M_i, K_i} \left\{ (\theta_i M_i^{\alpha_j} K_i^{1-\alpha_j})^{1 - \frac{1}{\epsilon}} - q_j M_i - r_j K_i \right\} \quad (232)$$

We first justify our formulas for the input shares (Equation 226). To do this, we solve for the firm’s optimal input choices. This is a concave problem, in which first-order conditions are necessary and sufficient. These conditions are

$$q_j = M_i^{-1} \alpha_j \left( 1 - \frac{1}{\epsilon} \right) (\theta_i M_i^{\alpha_j} K_i^{1-\alpha_j})^{1 - \frac{1}{\epsilon}} \quad (233)$$

$$r_j = K_i^{-1} (1 - \alpha_j) \left( 1 - \frac{1}{\epsilon} \right) (\theta_i M_i^{\alpha_j} K_i^{1-\alpha_j})^{1 - \frac{1}{\epsilon}}$$

Re-arranging, and substituting in $p_i = Y_i^{\frac{1}{\epsilon}}$, we derive

$$\alpha_j = \frac{\epsilon}{\epsilon - 1} \frac{q_j M_i}{p_i Y_i}$$

$$1 - \alpha_j = \frac{\epsilon}{\epsilon - 1} \frac{r_j K_i}{p_i Y_i} \quad (234)$$

Or, in words, that the materials elasticity is $\frac{\epsilon}{\epsilon - 1}$ times the ratio of materials input expenditures to sales. Observe also that, by re-arranging the two first-order conditions, we can
write expressions for production and the price

\[ Y = \left( \left( \frac{\epsilon - 1}{\epsilon} \right) \theta_i \left( \frac{\alpha_j}{q_j} \right)^{\alpha} \left( \frac{1 - \alpha_j}{r_j} \right)^{1 - \alpha_j} \right)^\epsilon \Rightarrow p = \left( \frac{\epsilon}{\epsilon - 1} \right) \theta_i^{-1} \left( \frac{q_j}{\alpha_j} \right)^{\alpha_j} \left( \frac{r_j}{1 - \alpha_j} \right)^{1 - \alpha_j} \]

(235)

and observe that \( \theta_i^{-1} \left( \frac{q_j}{\alpha_j} \right)^{\alpha_j} \left( \frac{r_j}{1 - \alpha_j} \right)^{1 - \alpha_j} \) is the firm’s marginal cost. Hence, we can define \( \mu = \frac{\epsilon}{\epsilon - 1} > 1 \) as the firm’s markup and write the shares as required:

\[ \alpha = \frac{q_j M_i}{p_i Y_i} \]

(236)

Finally, we now apply Equations 228 and 229 to calculate productivity. Assume that we observe materials expenditure \( q_j M_i \) and capital value \( p_{K,j} K_i \), where \( p_{K,j} \) is an (unobserved) price of capital. We find

\[ \log \tilde{\theta}_i = \left( 1 - \frac{1}{\epsilon} \right) \left( \log \theta_i - \alpha \log q_j - (1 - \alpha) \log p_{K,j} \right) \]

(237)

We finally observe that the industry-level means are

\[ \chi_j = \left( 1 - \frac{1}{\epsilon} \right) \left( \log \tilde{\theta}_j - \alpha \log q_j - (1 - \alpha) \log p_{K,j} \right) \]

(238)

where \( \log \tilde{\theta}_j \) is the mean of \( \log \theta_i \) over the industry. Hence,

\[ \log \hat{\theta}_i = \left( 1 - \frac{1}{\epsilon} \right) \log \theta_i \]

(239)

or our measurement captures physical TFP, up to scale.
E Additional Empirical Results

E.1 A Test for Coefficient Stability

Here, we study the bias that may arise from omitted variables in our estimation of the effect of narrative optimism on hiring, or $\delta_{OP}$ in Section 4.1, Equation 12, and Table 1. In particular, we apply the method of Oster (2019) to bound bias in the estimate of $\delta_{OP}$ under external assumptions about selection on unobservable variables and to calculate an extent of unobservable selection that could be consistent with a point estimate $\delta_{OP} = 0$ that corresponds to our null hypothesis (i.e., “narrative optimism is irrelevant for hiring”). We find that our results are highly robust by this criterion.

Set-up and Review of Methods. To review, our estimating equation is

$$\Delta \log L_{it} = \delta_{OP}^{opt} \gamma_i + \chi_j(i),t + \tau' X_{it} + \varepsilon_{it}$$  \hspace{1cm} (240)$$

Hiring and optimism are constructed as described in Section 3, at the level of firms and fiscal years. We treat firm and industry-by-time fixed effects as baseline controls that are necessary for interpreting the regression.\footnote{The latter, in particular, controls for the effect of fundamentals on hiring in our macroeconomic model. We leverage this interpretation of the biased estimate of $\delta_{OP}$ from a regression lacking this fixed effect in Appendix F.3.} As our main “discretionary” controls, we consider current and past TFP and lagged labor—that is, $X_{it} = \{\log \hat{\theta}_{it}, \log \hat{\theta}_{i,t-1}, \log L_{i,t-1}\}$. Under our baseline model, these controls help increase precision, as they are in principle observable variables that explain hiring (Corollary 1). Thus, in this Appendix, we will study the regression model in which the fixed effects are partialed out of both the outcome, main regression, and controls, as indicated below with the $\perp$ superscript:

$$\Delta \log L_{it}^\perp = \delta_{OP}^{opt} \gamma_i^\perp + \tau' X_{it}^\perp + \varepsilon_{it}^\perp$$  \hspace{1cm} (241)$$

The essence of the method proposed by Oster (2019), who builds on the approach of Altonji, Elder, and Taber (2005), is to extrapolate the change in the coefficient in interest upon the addition of control variables, taking into account the better fit (i.e., additional $R^2$) from adding the new regressors. To exemplify the logic, consider a case in which we first estimated Equation 241 without controls, obtaining a coefficient estimate of $\hat{\delta}_{NC}^{OP}$ and an $R^2$ of $\hat{R}_{NC}^2$, and then estimated the same equation with controls, obtaining a coefficient estimate of $\hat{\delta}_{C}^{OP}$ and an $R^2$ of $\hat{R}_{C}^2$. Both estimates are restricted to a common sample, for comparability. If $\hat{R}_{C}^2 = 1$, then (up to estimation error) we might presume that $\hat{\delta}_{C}^{OP} - \hat{\delta}_{NC}^{OP}$ estimates the entirety of the theoretically possible omitted variables bias, as there is no
remaining unmodeled variation in hiring. If $\hat{R}^2_C < 1$ and $\hat{R}^2_C - \hat{R}^2_{NC}$ is small (i.e., the controls did not greatly improve fit), then we might presume that the residual still contains unobserved variables that could contribute toward more bias—in other words, the observed omitted variables bias $\hat{\delta}^{OP} - \hat{\delta}^{OP}_{NC}$ is only a small fraction of what is possible.

To formalize this idea, Oster (2019) introduces two auxiliary parameters: $\lambda$ (the proportional degree of selection, called $\delta$ in the original paper), which controls the relative effect of observed and unobserved controls on the outcome, and $\bar{R}^2$, which is the maximum achievable fit of the regression with all (possibly bias-inducing) controls, presumed in the example above to be 1. Conditional on $R^2$, Oster (2019) proposes an intuitively reasonable (and, in special cases and under specific asymptotic arguments, consistent) estimator for the degree of selection required to induce a zero coefficient, $\hat{\lambda}^*$. Conditional on both $\bar{R}^2$ and $\lambda$, Oster (2019) also proposes a bias-corrected coefficient estimator, which is $\hat{\delta}^{OP}_{*P}$ in our language.

The key parameter that the researcher has to specify for the first calculation is $\bar{R}^2$: the proportion of variance in the outcome variable (hiring, net of firm and sector-by-time fixed effects) that can be explained by factors that correlate with the variable of interest (optimism) and explain the outcome variable. As the main source of omitted variation that could influence optimism and hiring is news about fundamentals, we benchmark $\hat{\bar{R}}^2$ by estimating a regression in which we include our base control set $X_{it} = \{\log \hat{\theta}_{it}, \log \hat{\theta}_{i,t-1}, \log L_{i,t-1}\}$ and control for two years of future fundamentals and labor choice, or

$$Z_{it} = \{\log \hat{\theta}_{i,t+1}, \log \hat{\theta}_{i,t+2}, \log L_{i,t+1}, \log L_{i,t+2}\}$$

This yields $\hat{\bar{R}}^2 = 0.459$. Oster (2019) also suggests as a benchmark that $\bar{R}^2$ could be taken as three times the $R^2$ in the controlled regression. We also report robustness to $\bar{R}^2_{\Pi} = 0.387$, three times the value of $R^2 = 0.129$ that we find in the controlled regression. Thus, our baseline value of $\hat{\bar{R}}^2 = 0.459$ is more demanding than that suggested by Oster (2019).

We finally construct the bias-corrected coefficients assuming $\lambda = 1$, or equal selection on unobservables and observables, for both values of $\bar{R}^2$.

**Results.** We report the results of this exercise in Table A6. Under our baseline value of $\hat{\bar{R}}^2 = 0.459$, we find that the degree of selection required to induced a zero coefficient is $\hat{\lambda}^* = 1.69$. This is well above the value of $\hat{\lambda}^* = 1$ that Oster (2019) suggests is likely to be conservative. Under the “three times $R^2$” benchmark, we obtain that $\hat{\lambda}^* = 2.15$. In both cases, we are robust to there being more selection on unobservables than on observables. According to Oster (2019), approximately 50% of the published top-journal articles in their sample are not robust to this extent of selection.

115
E.2 Alternative Empirical Strategy: CEO Change Event Studies

To further isolate variation in the narratives held by firms that is unrelated to fundamentals, we study the effects on hiring of changes in narratives induced by plausibly exogenous managerial turnover.

**Data.** To obtain plausibly exogenous variation in narratives held at the firm level, we will examine the year-to-year change in firm-level narratives stemming from plausibly exogenous CEO changes. To do this, we use the dataset of categorized CEO exits compiled by Gentry, Harrison, Quigley, and Boivie (2021). These data comprise 9,390 CEO turnover events categorized by the reason for the CEO exit. The categorization was performed using primary sources (e.g., press releases, newspaper articles, and regulatory filings) by undergraduate students in a computer lab, supervised by graduate students, with the final dataset checked by both a data outsourcing company and an additional student. We restrict attention to CEO exists caused by death, illness, personal issues, and voluntary retirements. Importantly, we exclude all CEO exits caused by inadequate job performance, quits, and forced retirement.

**The Effect of Optimism on Hiring.** We first revisit our empirical strategy for measuring the effect of optimism on firms’ hiring, using the CEO change event studies. For all firms $i$ and years $t$ such that $i$’s CEO leaves because of death, illness, personal issues or voluntary retirements, we estimate the regression equation

$$
\Delta \log L_{it} = \delta_{CEO}^{opt} + \psi_{opt,i,t-1} + \tau'X_{it} + \chi_{j(i),t} + \varepsilon_{it}
$$

This differs from our baseline Equation 12 by including parametric controls for lagged values of the narrative loadings, but removing a persistent firm fixed effect.\footnote{With a firm fixed effect, the regression coefficients of interest would be identified only from firms with multiple plausibly exogenous CEO exits.} If the studied CEO changes are truly exogenous, as we have suggested, then the narrative loadings of the new CEO are, conditional on the narrative loadings of the previous CEO, solely due to the differences in worldview across these two senior executives. Of course, CEO exits may be disruptive and reduce firm activity. Any time- and industry-varying effects of CEO exits via disruption are controlled for by the intercept of the regression $\chi_{j(i),t}$, since the equation is estimated only on the exit events. Moreover, any within-industry, time-varying, and idiosyncratic disruption is captured through our maintained productivity control. Under this interpretation, the coefficient of interest $\delta_{CEO}^{opt}$ isolates the effect of optimism on hiring purely via the channel of changing managements’ narratives.

We present our results in Table A22. We obtain estimates of $\delta_{CEO}^{opt}$ that are quantitatively...
similar to our estimates of $\delta^{OP}$ in Table 1 (columns 1, 2, and 3). In column 4, we estimate a regression equation on the full sample that measures the direct effect of CEO changes and its interaction with the new management’s optimism. Specifically, we estimate

$$\Delta \log L_{it} = \delta^{NoChange \text{opt}_{it}} + \delta^{Change (\text{opt}_{it} \times \text{ChangeCEO}_{it})} + \alpha^{Change \text{ChangeCEO}_{it}}$$

where $\text{ChangeCEO}_{it}$ is an indicator for our plausibly exogenous CEO change events. We find that CEO changes in isolation reduce hiring ($\alpha^{Change} < 0$) but also that the effect of optimism is magnified when it accompanies a CEO change ($\delta^{Change} > 0$). This is further inconsistent with a story under which omitted fundamentals lead us to overestimate the effect of optimism on hiring.

**Contagiousness from CEO Change Spillovers.** We next leverage changes in within-sector and peer-set optimism induced by plausibly exogenous CEO changes as instruments for the level of optimism within these groups. Concretely, we construct an instrument equal to the contribution toward optimism from firms whose CEOs changed for a plausibly exogenous reason, or

$$\overline{\text{opt}_{j(i),t-1}^{ceo}} = \frac{1}{|M_{j(i),t}|} \sum_{k \in M_{j(i),t}} \text{opt}_{k,t-1}$$

where $M_{j(i),t}$ is the set of firms in industry $j(i)$ at time $t$, and $M_{j(i),t}^{e}$ is the subset that had plausibly exogenous CEO changes. We construct the peer-set instrument $\overline{\text{opt}_{p(i),t-1}^{ceo}}$ analogously. We use $(\overline{\text{opt}_{j(i),t-1}^{ceo}}, \overline{\text{opt}_{p(i),t-1}^{ceo}})$ as instruments for $(\overline{\text{opt}_{j(i),t-1}}, \overline{\text{opt}_{p(i),t-1}})$ in the estimation of Equation 19. We present the corresponding estimates in Table A23. We find similar point estimates under IV and OLS, although the IV estimates are significantly noisier.

**E.3 Narrative Optimism, Beliefs, and Hiring**

In this appendix, we study whether narrative optimism, measured using text-analysis methods, matters for firm decisions conditional on firm-manager beliefs, measured from recorded managerial guidance. We find that narrative optimism and measured expectations each have predictive power conditional on the other for explaining hiring and capital investment. These results suggest that textual optimism captures aspects of managers’ latent beliefs not captured in traditional measurement of expectations (here, in guidance data).

**Data.** We collect data from IBES (the International Brokers’ Estimate System) on quantitative forecasts by company managers for three statistics: sales, capital expenditures (CAPX), and earnings per share (EPS). As described in Section 3.1, we restrict to the
first recorded forecast per fiscal year of that year’s variable. When managers’ guidance is reported as a range, we code a point-estimate forecast as the range’s midpoint. For each variable \( Z \in \{ \text{Sales, Capx, Eps} \} \), we calculated the manager’s predicted growth for fiscal year \( t \) as

\[
\text{ForecastGrowth}_Z^{it} = \log \text{GuidanceFor}_X^{it} - \log Z_{i,t-1}
\]  

For example, \( \text{GuidanceForSales}^{it} \) is the manager’s earliest recorded guidance within fiscal year \( t \) for fiscal-year \( t \) sales, and \( \text{Sales}_{i,t-1} \) are recorded sales from fiscal year \( t - 1 \). Textual narrative optimism \( \text{opt}^{it} \) is measured as in our main analysis.

**Empirical Strategy.** We re-create our main regression model, predicting hiring by \( \text{opt}^{it} \) conditional on firm fixed effects and industry-by-time fixed effects. We now include, as control variables, each of the \( \text{ForecastGrowth}_Z^{it} \) variables:

\[
\Delta \log L^{it} = \delta^{\text{OP}} \text{opt}^{it} + \delta^Z \text{ForecastGrowth}_Z^{it} + \gamma_i + \chi_{j(i),t} + \varepsilon^{it}
\]

The coefficient \( \delta^{\text{OP}} \) measures the difference in hiring between textually optimistic and non-optimistic firms, holding fixed forecasted growth about variable \( Z \) (and the fixed effects). The coefficient \( \delta^Z \) measures the marginal effect of forecasted growth, in variable \( Z \), on hiring, holding fixed whether the firm is optimistic or pessimistic (and the fixed effects). We also estimate a variance with net investment, or \( \Delta \log K^{it} \), on the left-hand side.

**Results.** Table A24 shows the results when hiring is the outcome. We find that forecasted sales, CAPX, and earnings growth have positive effects of hiring, the first two of which are statistically significant (columns 2-4). Nonetheless, conditional on these variables, optimism has a positive effect on hiring of comparable magnitude to the baseline (column 1). The effect is statistically significant conditional on forecasted sales and CAPX growth (respectively, \( t = 1.80 \) and \( t = 4.54 \)). Both optimism and forecasted EPS growth are insignificant predictors of hiring on the small (\( N = 1290 \)) sample for which we can obtain EPS growth forecasts.

To compare the magnitudes of effects, we can calculate standardized coefficients. These have units of the effect of a one-standard-deviation change in the regressor on standard deviations of the outcome. For column 2, the standardized coefficient on textual optimism is 0.057 (SE: 0.0030) and the coefficient on predicted sales growth is 0.213 (SE: 0.0329). In this sense, predicted sales growth, for the subset of firms for which it is available, explains larger variations in hiring than textual optimism; but nonetheless, textual optimism has a statistically and economically significant effect.

Table A25 shows analogous results when net capital investment is the outcome. As with hiring, we verify that predicted sales and CAPX growth have statistically significant, positive
effects on capital investment, and that optimism has a positive effect conditional on these variables. Effects on the sub-sample with earnings guidance are noisy, for both the effects of optimism and the effects of forecasts.

Discussion. We interpret our results in a model in which textual optimism, opt_{it}, is one measurement of a non-fundamental shifter in firm managers’ beliefs. We validate this interpretation in the paper by showing that opt_{it}: (i) predicts hiring, as reviewed above in this note; (ii) does not predict future positive firm performance; and (iii) does correlate with optimistic manager forecasts, when measured in a variety of ways. We interpret managerial forecasts, about a variety of firm-specific variables, as alternative possible measurements of beliefs and their non-fundamental component. We are agnostic, more or less, about which of these measures explains more variation in firm actions or does so more precisely.

More broadly, while forecasts are quantitative, and provide hard information about managers’ beliefs, they also capture at best only one or two moments of a probability distribution. By contrast, our measures of text all us to capture information about managers’ beliefs that they do not express numerically, i.e., we capture soft information about managers’ beliefs (Liberti and Petersen, 2019). We find that this soft aspect of managers’ beliefs is important for explaining their decisions conditional on hard information. This is consistent with extensive economic and psychological evidence that humans do not naturally think probabilistically (see e.g., Tversky and Kahneman, 1973). Language may reflect nuances not present in the forecasts. These nuances are actually what we want to map to economic models, where we (economists) introduce statistical beliefs to model sentiment. This is the sense in which language might measure aspects of beliefs that are not captured in “measured beliefs.” In this way, our results relate to a literature focusing on the decision-relevance of measured beliefs (Gennaioli, Ma, and Shleifer, 2016). They are moreover consistent with the literature focusing on the decision-relevance of textually measured firm-level variables including reported risks (Hassan, Hollander, Van Lent, and Tahoun, 2019) and reported uncertainty (Handley and Li, 2020).

E.4 State-Dependent Effects of Sentiment

Our main empirical framework assumes that the effect of narrative sentiment on hiring does not depend on previous sentiment. As one concrete example, this rules out the possibility that switching from relative optimism to relative pessimism has a larger effect than remaining equally pessimistic for two consecutive periods. To test for such state-dependent effects, we
estimate augmented regression equations of the form:

\[
\Delta \log L_{it} = \delta_0 \text{sentiment}_{it} + \delta_1 \text{sentiment}_{i,t-1} + \\
\delta_2 (\text{sentiment}_{it} \times \text{sentiment}_{i,t-1}) + \gamma_i + \chi_{j(i),t} + \tau' X_{it} + \varepsilon_{it}
\] (247)

where sentiment\(_{it}\) is our continuous measure of firm sentiment in language, (\(\gamma_i, \chi_{j(i),t}\)) are fixed effects at the firm and industry-by-time levels, and \(X_{it}\) is a vector of controls. This model allows for the marginal effect of this fiscal year’s sentiment to depend on the level of the previous fiscal year’s sentiment. In particular, if \(\delta_2 > 0\), and the marginal effect of sentiment is positive, then this marginal effect is higher for a previously positive firm; if \(\delta_2 < 0\), and the marginal effect of sentiment is positive, then this marginal is lower for a previously positive firm.

Table A26 shows our results, for different choices of controls. We find significant evidence of positive marginal effects for sentiment\(_{it}\) and \(\delta_2 < 0\), or larger marginal effects when lagged sentiment is low. This asymmetry is quantitatively small, however, in the following sense. The standard deviation of sentiment\(_{i,t-1}\) is 1.14. Using the estimates of column 1, a one-standard-deviation increase in sentiment, starting from sentiment\(_{i,t-1} = 0\), decreases the marginal effect of sentiment\(_{it}\) from 0.022 to 0.016.

### E.5 Measuring Contagiousness via Granular Instrumental Variables

As an alternative strategy to estimate contagiousness, we apply the methods of Gabaix and Koijen (2020) to construct “granular variables” that aggregate idiosyncratic variation in large firms’ narrative loadings. We find evidence that the idiosyncratic optimistic updating of large firms induces optimistic updating, a form of contagiousness.

**Constructing the Granular Measures.** We construct our granular instruments via the following algorithm. We first estimate a firm-level updating regression that controls non-parametrically for aggregate trends and parametrically for firm-level conditions. Specifically, we estimate

\[
\text{opt}_{it} = \tau' X_{it} + \chi_{j(i),t} + \gamma_i + u_{it}
\] (248)

where \(\chi_{j(i),t}\) is an industry-by-time fixed effect (sweeping out industry-specific aggregate shocks), \(\gamma_i\) is a firm fixed effect (sweeping out compositional effects), and \(X_{it}\) is the largest vector of controls used in the analysis of Section 4.1, consisting of: lagged log employment, current and lagged log TFP, log stock returns, the log book to market ratio, and leverage. We construct the empirical residuals \(\hat{u}_{it}\). To construct the aggregate granular variable, \(\bar{\text{opt}}^\text{p,sw}_i\),
we take a sales-weighted average of these residuals:

$$\bar{\text{opt}}_{t,sw}^{g,sw} = \sum_{i} \frac{\text{sales}_{it}}{\sum_{i} \text{sales}_{it}} \hat{u}_{it}$$  \hfill (249)

To construct an industry-level granular variable, $\text{opt}_{t,sw}^{g,sw}$, we take the leave-one-out sales-weighted average of the $\hat{u}_{it}$:

$$\text{opt}_{t,sw}^{g,sw} = \sum_{i' : j(i) = j(i') \land i' \neq i} \frac{\text{sales}_{i't}}{\sum_{i} \text{sales}_{i't}} \hat{u}_{i't}$$  \hfill (250)

We also construct aggregate and industry (leave-one-out) averages of $\text{opt}_{it}$ for comparison. We denote these variables as $\text{opt}_{t,sw}$ and $\text{opt}_{j(i),t,sw}$, respectively.

**Empirical Strategy.** At the aggregate level, we first consider a variant of our main model Equation 18, but with one of the sales-weighted variables $Z_{t} \in \{\text{opt}_{t,sw}, \text{opt}_{t,sw}^{g,sw}\}$:

$$\text{opt}_{it} = u \text{opt}_{i,t-1} + s Z_{t-1} + r \Delta \log Y_{t-1} + \gamma_{i} + \varepsilon_{it}$$  \hfill (251)

The coefficient $s$ measures contagiousness with respect to the sales-weighted measures of optimism. We estimate Equation 251 by OLS, and also estimate a version in which the granular variable $\text{opt}_{t,sw}^{g,sw}$ is an instrumental variable for the raw sales-weighted average $\text{opt}_{t,sw}$.

Similarly, at the industry level, we estimate the model

$$\text{opt}_{it} = u_{\text{ind}} \text{opt}_{i,t-1} + s_{\text{ind}} Z_{j(i),t-1} + r_{\text{ind}} \Delta \log Y_{j(i),t-1} + \gamma_{i} + \chi_{t} + \varepsilon_{it}$$  \hfill (252)

for $Z_{j(i),t} \in \{\text{opt}_{j(i),t,sw}^{sw}, \text{opt}_{j(i),t,sw}^{g,sw}\}$. As above, we estimate this first via OLS for each outcome variable, and then via IV where the granular variable $\text{opt}_{j(i),t,sw}^{g,sw}$ is an instrument for the raw sales-weighted average $\text{opt}_{j(i),t,sw}^{sw}$.

**Results.** We present our results in Table A27. First, studying aggregate contagiousness, we find strong evidence that $s > 0$ when measured with the raw sales-weighted average or its granular component (columns 1 and 2). We moreover find significant evidence of $s > 0$ in the IV estimation (column 3). Our IV point estimate of $\hat{s} = 0.308$ greatly exceeds the OLS estimate of $\hat{s} = 0.0847$.

At the industry level, we find strong evidence of contagiousness via the sales-weighted measure (column 4). We find imprecise estimates, centered around 0, for contagiousness measured with the granular variable (column 5) or via the granular IV (column 6). However, the granular IV estimate is noisily estimated and is not significantly different from the point estimate of column 4.
F Additional Details on Model Quantification

F.1 Solution of Model With Persistent Fundamentals

We first provide the exact solution of the model when fundamentals follow an AR(1) process. We build on the analysis of Appendix B.5, which allows for (among other features) persistent fundamentals.

Law of Motion for Output. Log aggregate productivity follows the process

\[ \log \theta_t = (1 - \rho) \mu + \rho \log \theta_{t-1} + \sigma \zeta_t \]  

(253)

with \( \zeta_t \sim N(0, 1) \) IID. We continue to assume, as in our main analysis, that there are two narratives associated with high and low values of \( \mu \), \( \mu_O > \mu_P \), while the true value is \( \mu = 0 \). Proposition 13 establishes that equilibrium can be written as (\( f \) does not depend on \( \theta_{t-1} \) here as all agents believe persistence is \( \rho \))

\[ \log Y_t = a_0 + a_1 \log \theta_t + a_2 \log \theta_{t-1} + f(Q_t) \]  

(254)

where we normalize \( a_0 = 0 \). We define the fundamental component of output as \( \log Y_t - f(Q_t) \):

\[ \log Y_t^f = a_1 \log \theta_t + a_2 \log \theta_{t-1} \]  

(255)

Subtracting \( \rho \log Y_t^f \) from both sides, the above becomes an ARMA(1, 1) process:

\[ \log Y_t^f - \rho \log Y_{t-1}^f = a_1 \sigma \zeta_t + a_2 \sigma \nu_{t-1} \]  

(256)

It remains to solve for the coefficients (\( a_1, a_2 \)). In particular, Equations 172 and 173 give the fixed-point equations which these coefficients must solve. We can simplify these fixed point equations considerably in the case with optimism and pessimism about means and compute \( \delta_{t,k} \) for \( k \in \{O, P\} \):

\[ \delta_{t,k} = \frac{1}{\alpha} \left[ \log \left( \frac{1 - \frac{1}{\epsilon}}{\frac{1 + \psi}{\alpha}} \right) + \frac{1 + \psi}{\alpha} \left[ \log \left( \frac{1}{\frac{1 + \psi}{\alpha}} \right) + (1 - \kappa) \left( \log \gamma_i + \kappa \log \theta_t + (1 - \kappa) \left( (1 - \rho) \mu_k + \rho \log \theta_{t-1} \right) \right] \right] 
- \frac{1}{2} \left( \frac{1 + \psi}{\alpha} \right)^2 \left( \sigma_{\theta|s}^2 + \sigma_{\gamma|s}^2 \right) + \frac{1}{2} a_1^2 \left( \frac{1}{\epsilon} - \gamma \right)^2 \sigma_{\theta|s}^2 
+ \left( \frac{1}{\epsilon} - \gamma \right) \left[ a_0 + a_1 \left( \kappa \log \theta_t + (1 - \kappa) \left( \log \gamma_i + \kappa \log \theta_t + (1 - \kappa) \left( (1 - \rho) \mu_k + \rho \log \theta_{t-1} \right) \right) \right] + a_2 \log \theta_{t-1} + f(Q_t) \right] \]  

(257)
Here, we have used the fact that posterior variances and perceived persistence are the same for the two narratives, and the fact that \( \mu(e_k, \theta_{t-1}) = (1 - \rho) \mu_k + \rho \log \theta_{t-1} \). Therefore,

\[
a \delta_{OP} := \delta_{t,O} - \delta_{t,P} = \frac{1}{1 + \psi - \alpha} + \frac{1}{\epsilon} \left( \frac{1 + \psi}{\alpha} + \left( \frac{1}{\epsilon} - \gamma \right) a_1 \right) (1 - \kappa) (1 - \rho) (\mu_O - \mu_P) \tag{258}
\]

is the (time-invariant) average difference in actions between optimists and pessimists, as we identify in the data.

Next, taking \( \delta_t(e_1) = \delta_{t,P} \) and \( Q_t \) as the fraction of optimists, we write Equation 173 as

\[
\log Y_t = \delta_{t,P} + \frac{1}{2} \epsilon - \frac{1}{\epsilon} \hat{\sigma}^2 + \frac{\epsilon}{\epsilon - 1} \log \left( Q_t \exp \left\{ \frac{\epsilon - 1}{\epsilon} \alpha \delta_{OP} \right\} \right) \tag{259}
\]

Substituting in the expression for \( \delta_{t,P} \), we can write the above up to a constant \( C \) that does not depend on \( \log \theta_t, \log \theta_{t-1}, Q_t \) as

\[
\log Y_t = C + \frac{1}{1 + \psi - \alpha} + \frac{1}{\epsilon} \left[ \frac{1 + \psi}{\alpha} + \left( \frac{1}{\epsilon} - \gamma \right) a_1 \right] \log \theta_t \\
+ \frac{1}{1 + \psi - \alpha} + \frac{1}{\epsilon} \left[ \frac{1 + \psi}{\alpha} (1 - \kappa) \rho + \left( \frac{1}{\epsilon} - \gamma \right) (a_1 (1 - \kappa) \rho + a_2) \right] \log \theta_{t-1} \tag{260}
\]

To obtain the coefficients in our desired representation, first note that we can write

\[
f(Q_t) = \frac{\epsilon}{\epsilon - 1} \log \left( Q_t \exp \left\{ \frac{\epsilon - 1}{\epsilon} \alpha \delta_{OP} \right\} \right) - \frac{\epsilon}{\epsilon - 1} \log \left( \frac{1}{2} \exp \left\{ \frac{\epsilon - 1}{\epsilon} \alpha \delta_{OP} \right\} \right) \tag{261}
\]

This is the same form as our main analysis, with a normalization such that \( f(1/2) = 0 \). Next, from matching coefficients, and noting the definition of \( \omega = (1/\epsilon - \gamma)/((1 + \psi - \alpha)/\alpha + 1/\epsilon) \),

\[
a_1 = \frac{1}{1 - \kappa \omega} \frac{1 + \psi}{\alpha} - \frac{1 + \psi}{\alpha} + \frac{1}{\epsilon} \tag{262}
\]

Finally, from matching coefficients for \( a_2 \),

\[
a_2 = \frac{1}{1 - \omega} \frac{1}{1 + \psi - \alpha} + \frac{1}{\epsilon} \left[ \frac{1 + \psi}{\alpha} + \left( \frac{1}{\epsilon} - \gamma \right) a_1 \right] (1 - \kappa) \rho \tag{263}
\]

**Updating Rule.** We use the Linear-Associative-Contagious Updating rule introduced as the Main Case (Equation 29), with a normalization. More specifically, we assume transition
probabilities

\[ P_H^O (\log Y, Q, \varepsilon) = [u + r \log Y + sQ + C_P + \varepsilon]_0^1 \]
\[ P_P^H (\log Y, Q, \varepsilon) = [-u + r \log Y + sQ + C_P + \varepsilon]_0^1 \] (264)

We choose \( C_P \) such that an economy with neutral fundamentals (log \( \theta_t = \log \theta_{t-1} = 0 \)), equal optimists and pessimists (\( Q = 1/2 \)), and no narrative shocks (\( \varepsilon = 0 \)) continues to have equal optimists and pessimists. Specifically, this implies \( C_P = \frac{1 - s}{2} \).

F.2 Calibration Methodology

To calibrate the model, we proceed in four steps.

1. **Setting macro parameters.** We first set (\( \epsilon, \gamma, \psi, \alpha \)). In Section 7.1 and Table 6, we describe our baseline method based on matching estimates of the deep parameters from the literature. We also consider two other strategies as robustness checks. First, to target estimated fiscal multipliers in the literature, we use the same external calibration of \( \alpha \) (returns to scale) and \( \epsilon \) (elasticity of substitution), and set (\( \gamma, \psi \)) to match the desired multiplier. Since the exact choice of these parameters is arbitrary subject to obtain the correct multiplier, we normalize \( \gamma = 0 \) and vary only \( \psi \). Second, we match an estimate of the multiplier implied by our own data and an exact formula for the omitted variable bias incurred in estimating the effect of optimism on hiring without controlling for general-equilibrium effects via a time fixed effect. We outline that strategy for estimating the multiplier in Section F.3 below, and we map this to deep parameters exactly as described in our method for matching the literature’s estimated multiplier.

2. **Calibrating the effect of optimism on output.** We observe that, conditional on (\( \epsilon, \gamma, \psi, \alpha \)) and an estimate of \( \delta^{OP} \), we have identified \( f(Q_t) \) as defined in Equation 261. We take our estimate of \( \delta^{OP} \) from column 1 in Table 1. This regression identifies \( \delta^{OP} \) for the reasons described in Corollary 1.

3. **Calibrating the statistical properties of fundamentals (\( \kappa, \rho, \sigma \)).**

   (a) **Computing fundamental output.** We construct a cyclical component of output, \( \log \hat{Y}_t \), as band-pass filtered US real GDP (Baxter and King, 1999). We apply our estimated function \( f \) to our measured time series of optimism (see Figure 1).

   \footnote{Specifically, we filter to post-war quarterly US real GDP data (Q1 1947 to Q1 2022). We use a lead-lag length of 12 quarters, a low period of 6 quarters, and a high period of 32 quarters. We then average these data to the annual level.}
to get an estimated optimism component of output. we then calculate
\[ \log \hat{Y}_t^f = \log \hat{Y}_t - \hat{f}(\hat{Q}_t) \] (265)

(b) *Estimating the ARMA representation.* Using our 24 annual observations of \( \log \hat{Y}_t^f \),
we estimate a Gaussian-errors ARMA(1,1) model via maximum likelihood. Our
point estimates are
\[ \log \hat{Y}_t^f - 0.086 \log \hat{Y}_t^f = .0078(\zeta_t + .32 \nu_{t-1}) \] (266)

This implies \( \rho = 0.086, a_1\sigma = .0078, \) and \( a_2\sigma = .32. \rho \) is therefore identified
immediately.

(c) *Calibrating \((\kappa, \sigma)\).* We search non-linearly for values of \((\kappa, \sigma)\) that satisfy \( a_1\sigma =
0.0078 \) and \( a_2\sigma = 0.32. \) There is a unique such pair, reported in Table 6, which
also is therefore the maximum likelihood estimate of \((\kappa, \sigma)\).

4. *Calibrating the updating rule \((u, r, s, \sigma_\varepsilon^2)\).* The coefficients of the LAC updating model
are estimated in column 1 of Table 4. Conditional on the previous calibration, we set
\( \sigma_\varepsilon^2 \) so that within model \( Q_t \) has the same standard deviation as the aggregate optimism
time series, which is 0.0533.

To calibrate the variant model with multi-dimensional narratives, we follow steps 1-3
exactly as above combined with a different procedure for step 4 described below:

4’. *Calibrating the multi-dimensional updating rule \(((\beta^k, u^k, r^k, s^k)_{k=1}^K, \sigma_\varepsilon^2)\).* To map theory
to data, we first transform each continuous narrative loading variable \( \hat{\lambda}_{k, i, t} \) (indexed by
narrative identifier \( k \), firm \( i \), and time period \( t \)) into a binary indicator for being above
the sample median,
\[ \hat{\lambda}_{k, i, t}^b = \mathbb{I}\left[ \hat{\lambda}_{k, i, t} \geq \text{med}\left(\hat{\lambda}_{k, i, t}\right) \right] \in \{0, 1\} \]

We study the 2 decision-relevant Shiller (2020) narratives and 11 decision-relevant topic
narratives indicated in Table 3. We let \( k \in \{1, \ldots, 13\} \) index these narratives below.

(a) *Calibrating the constellation weights \( \beta \).* To estimate the constellation weights, we
first regress optimism at the firm level on the binary indicators for each of the
selected narratives, conditional on firm and industry-by-time fixed effects:
\[ \text{opt}_{i, t} = \sum_{k=1}^{13} \tau^k \hat{\lambda}_{k, i, t}^b + \gamma_i + \chi_{j(i), t} + \nu_{i, t} \] (267)

For all \( k \) such that \( \tau^k < 0, \) we re-normalize the narrative to \( 1 - \hat{\lambda}_{k, i, t}^b \) (i.e., an
indicator for being below-median), such that all narratives positively contribute toward the probability of being optimistic. We finally construct an estimator of \( \hat{\beta}_k \) which re-normalizes the regression coefficients above to sum to one,

\[
\hat{\beta}_k = \frac{|\hat{\tau}_k|}{\sum_{j=1}^{13} |\hat{\tau}_j|}
\]  

(b) *Calibrating the updating parameters* \((u^k, r^k, s^k)\) and \(\sigma_e^2\). To estimate the updating rule parameters, we take the \(u^k, r^k,\) and \(s^k\) parameters from Figure A9, flipping the sign of associativeness if we flipped \(\tau^k\) in step 4′(a). Conditional on the previous calibration, we set \(\sigma_e^2\) so that within model \(Q_t\) has the same standard deviation as the aggregate optimism time series, which is 0.0533.

### F.3 Estimating a Demand Multiplier in Our Empirical Setting

Here, we describe a method for estimating a demand multiplier in our data on optimism and firm hiring. This circumvents the step of external calibration for the multiplier, but relies on correct specification of the time-series correlates of aggregate optimism. Reassuringly, this method yields a general-equilibrium demand multiplier that is comparable to our baseline calibration and our literature-derived calibration.

**Mapping the Model to Data.** Extending Corollary 1 with the calculations of Appendix B.5 and Appendix F.1, we first observe that firms’ hiring can be written in equilibrium as

\[
\Delta \log L_{it} = \tilde{c}_{0,i} + \tilde{c}_{10} \log \theta_t + \tilde{c}_{11} \log \theta_{t-1} + \tilde{c}_{2} f(Q_t) + \tilde{c}_{3} \log \theta_{it} + \tilde{c}_{4} \log L_{i,t-1} + \delta^{OP} \lambda_{it} + \zeta_{it}
\]

where \(\zeta_{it}\) is an IID normal random variable with zero mean and \(\lambda_{it}\) is the indicator for having adopted the optimistic narrative.

In the data, our estimating equation without control variables had the following form

\[
\Delta \log L_{it} = \gamma_i + \chi_{j(i),t} + \delta^{OP} \text{opt}_{it} + z_{it}
\]

This maps to the structural model with \(\gamma_i = \tilde{c}_{0,i},\ \chi_{j(i),t} = \tilde{c}_{10} \log \theta_t + \tilde{c}_{11} \log \theta_{t-1} + \tilde{c}_{2} f(Q_t)\), and \(z_{it} = \zeta_{it} + \tilde{c}_{3} \log \theta_{it} + \tilde{c}_{4} \log L_{i,t-1}\). Under the hypothesis that \(\mathbb{E}[z_{it}\text{opt}_{it}] = 0\), then the OLS regression of \(\Delta \log L_{it}\) on \(\text{opt}_{it}\), conditional on the indicated fixed effects, identifies \(\delta^{OP}\).

We consider now an alternative regression equation which is a variant of the above specification without the time fixed effect and with parametric controls for aggregate TFP:

\[
\Delta \log L_{it} = \gamma_i + \delta^{OP} \text{opt}_{it} + \tilde{c}_{10} \log \theta_t + \tilde{c}_{11} \log \theta_{t-1} + \tilde{z}_{it}
\]
Observe that the new residual, relative to the old residual, is contaminated by the equilibrium effect of optimism. That is, \( \tilde{z}_{it} = z_{it} + \tilde{c}_2 f(Q_t) \). To refine this further, we apply the linear approximation \( f(Q_t) \approx \alpha \delta_{OP} Q_t + \omega Q_t \) and the observation that \( \tilde{c}_2 = \omega \), so we can write \( \tilde{z}_{it} = z_{it} + \alpha \omega \delta_{OP} Q_t \).

We now derive a formula for omitted variables bias in the estimate of \( \delta_{OP} \) from an OLS estimation of Equation 271. Let \( X \) denote a finite-dimensional matrix of data on \( \text{opt}_{it} \), firm-level indicators (i.e., the regressors corresponding to the firm fixed effects), and current and lagged aggregate TFP. Similarly, let \( Y \) be a finite-dimensional matrix of data on \( \Delta \log L_{it} \). The OLS regression coefficient in this finite sample is \( \hat{\delta} = \left( X'X \right)^{-1}X'Y \). Using the standard formula for omitted variables bias:

\[
\mathbb{E}[\hat{\delta} | X] = \delta_{OP} + \left( (X'X)^{-1} \mathbb{E}[X'Q|X] \right) \frac{\alpha \omega}{1 - \omega} \delta_{OP}
\]

\[
= \delta_{OP} \left( 1 + \frac{\alpha \omega}{1 - \omega} \left( (X'X)^{-1} \mathbb{E}[X'Q|X] \right) \right)
\]

(272)

where \( Q \) is the vector of observations of \( Q_t \). We can then observe that:

\[
(X'X)^{-1} \mathbb{E}[X'Q|X] = \mathbb{E} \left[ (X'X)^{-1} X'Q \right]
\]

(273)

Which is the (expected) OLS estimate of \( \beta \) in the following regression:

\[
Q_t = \gamma_i + \beta_Q^Q \text{opt}_{it} + \beta_Q^Q \log \theta_t + \beta_{\theta-1}^Q \log \theta_{t-1} + \varepsilon_t
\]

(274)

But we observe that, averaging both sides, that \( \gamma_i = \beta_Q^Q = \beta_{\theta-1}^Q = 0 \) and \( \beta_Q^Q = 1 \). Thus, \( (X'X)^{-1} \mathbb{E}[X'Q|X] \) = 1. We therefore obtain that:

\[
\mathbb{E}[\hat{\delta} | X] = \delta_{OP} \left( 1 + \frac{\alpha \omega}{1 - \omega} \right)
\]

(275)

Hence, given a population estimate of the \textit{biased} OLS estimate and an external calibration of \( \alpha \), we can pin down the complementarity \( \omega \) and the multiplier \( \frac{1}{1 - \omega} \). Naturally this strategy relies on correctly measuring aggregate TFP as measurement error in that variable would contaminate this estimation. Moreover, it requires us to assume that all variation in aggregate output that is not due to TFP is due to optimism or forces entirely orthogonal to optimism; in view of our running assumption that the spread of optimism is associative, these other forces therefore also have to be completely transitory, lest they be incorporated into current optimism via associative updating in a previous period. These assumptions are strong and are why we do not adopt this strategy for our main quantitative analysis.
Nevertheless, we will find similar results, as we now describe.

Empirical Application and Results. To operationalize this in practice, we compare estimates of Equation 270 and 271. For the latter, we proxy TFP using the cyclical component of both capacity adjusted and capacity un-adjusted TFP using the data of Fernald (2014).46 We moreover maintain the assumption of $\alpha = 1$, or constant returns to scale, to map our estimates back to implied multipliers.

Our results are reported in Table A28, along with the associated values of complementarity $\omega$ and the multiplier $\frac{1}{1-\omega}$. Using capacity-adjusted and unadjusted TFP, we respectively obtain estimates of 1.46 and 1.37 for the multiplier. These are lower than our baseline estimate, but comparable to our estimates based on structural modeling in the literature. Both estimates are below our baseline calibration of 1.96 but above our multiplier-literature calibration of 1.33. In Table A19, we report our quantitative results under the assumed multiplier of 1.46. We find that, as expected, these estimates imply an role for optimism that is an intermediate between the baseline and multiplier-literature calibrations.

46Mirroring our filtering of US real GDP, we apply the Baxter and King (1999) band-pass filter to post-war quarterly data using a lead-lag length of 12 quarters, a low period of 6 quarters, and a high period of 32 quarters. We then average these data to the annual level.
Our Analysis and Shiller’s *Narrative Economics*

Shiller (2017, 2020) introduces the notion of narrative economics and identifies “Seven Propositions of Narrative Economics” as a basis for the theoretical and empirical investigation of narratives. In this section, we discuss our work, how our modeling of narratives relates to Shiller’s ideas, and the relationship of our modeling, measurement, and results with these propositions. In the process, we highlight how these propositions have informed our analysis, discuss how our analysis contributes new insights, and propose avenues for future work to more fully understand narratives and the macroeconomy.

**G.1 The modeling of Narratives**

We first describe how our modeling and measurement of narratives are designed to capture the salient features of narratives that Shiller (2020) introduces in the preface:

In using the term narrative economics, I focus on two elements: (1) the word-of-mouth contagion of ideas in the form of stories and (2) the efforts that people make to generate new contagious stories or to make stories more contagious. First and foremost, I want to examine how narrative contagion affects economic events. The word narrative is often synonymous with story. But my use of the term reflects a particular modern meaning given in the Oxford English Dictionary: “a story or representation used to give an explanatory or justificatory account of a society, period, etc.” Expanding on this definition, I would add that stories are not limited to simple chronologies of human events. A story may also be a song, joke, theory, explanation, or plan that has emotional resonance and that can easily be conveyed in casual conversation.

To map this verbal definition to our framework (see Section 2 for the formal details and notation), consider the following simple verbal rationale for our modeling approach. There is a latent space of economic fundamentals (demand for goods) and endogenous outcomes (aggregate output). An agent has some beliefs about economic fundamentals and corresponding endogenous outcomes ($\pi$). They are told the following simple story by another agent about the economy: “I didn’t hire ($x$) because aggregate output ($Y$) will be low because demand ($\theta$) is weak.” This might cause the agent to believe this story that demand is weak and adopt this narrative (placing weight $\lambda$ on the implied distribution of fundamentals). Moreover, if many of their friends tell them the story, they might be more positively inclined to believe it. Of course, the agent doesn’t listen to the story blindly: they can see if demand was previously low (and might even have information about demand from their personal economic
activities $I$) and might regard such a story is fanciful if their own experience contradicts this claim. At the end of this process of contemplation, they update their own weight on the narrative (via $P$) and arrive at their new belief ($\pi'$).

Of course, the actual realization of output depends on the circulation of narratives in the population ($Q$). If an agent believes the “demand is weak” narrative, then they will curtail their hiring. Knowing this, other agents—even if they do not believe that latent demand is weak—will believe that others will curtail their hiring, so that realized demand will be weak. Then, knowing this, all agents further cut hiring. This paradox of thrift induces a hierarchy of higher-order expectations regarding realized demand induced by the distribution of narratives. This converges to a fixed point ($Y^*(Q) : \Theta \rightarrow \mathcal{Y}$) describing the mapping of demand into aggregate output under the prevailing circulation of narratives.

Thus, while the primitive narrative began as a story about the strength of demand, in equilibrium it takes on a meaning as not only describing exogenous economic outcomes, but also endogenous economic outcomes. Concretely, given an equilibrium mapping, the narrative endogenously induces the joint belief $N^* \in \Delta(\Theta \times \mathcal{Y})$ given by $N^*(\theta, Y) = N(\theta) \times I[Y = Y^*(\theta)]$. Importantly, the distribution of narratives $Q$ and endogenous outcomes $Y$ then shape the distribution of narratives tomorrow $Q'$. The resulting joint dynamics of narratives and endogenous outcomes are the subject of the theoretical and quantitative analysis of this paper.

To ensure that we measure narratives, trace their impact on decisions and study their spread, we operationalize this empirically by measuring narratives in agents’ use of language by employing natural language processing methods that we have described in Section 3.1. This allows us to use our framework to test if these text-based proxies for narratives shape actions and spread across agents. As described in Section 4, we find strong evidence of these premises.

We are, however, essentially silent about the more fundamental determinants of how something comes to be a narrative or what makes a narrative contagious. As a result, we do not speak to the issue of narrative generation suggested by Shiller. We do have one empirical result that hints that firms use narratives to persuade financial analysts. In our IBES strategy, we found that optimistic firms significantly overestimate their sales relative to pessimistic firms. However, we found much weaker evidence that analysts believe that firms are performing this overestimation. As a result, we take this as tentative evidence that firms manage to persuade analysts of their predictions. We view further exploration of this issue as an interesting angle for future work.
G.2 Our Work and Shiller’s Seven Propositions

Proposition 1: Epidemics Can Be Fast or Slow, Big or Small. The model developed in this paper allows for various speeds of narrative dynamics as well as their size and economic impact. Shiller, drawing on the epidemiology literature, identifies two parameters as particularly important in determining these features: the contagion rate and the recovery rate. Viewed through this lens, our structural model from Section 5 postulates a recovery rate of \( 1 - P_O(\log Y_t, Q_t) \) and a contagion rate of \( P_P(\log Y_t, Q_t) \). Thus, the fundamental parameters determining stubbornness \( u \), associativeness \( r \) and contagiousness \( s \) are key determinants of the speed and size of narrative epidemics within our model.

Yet further, by moving beyond a purely epidemiological model and studying the two-way feedback between narratives and endogenous outcomes, we endogenize these rates as equilibrium outcomes by characterizing the equilibrium map \( Q_t, \theta_t \mapsto Y_t \). Thus, the parameters of \( P_O \) and \( P_P \) as well as those determining the information and strategic interaction in the economy affect the contagion and recovery rates in ways that we have characterized. Most interestingly, beyond affecting the quantitative features of narrative dynamics (such as speed and size), accounting for the dynamic complementarity of narratives affects their qualitative features. Concretely, these same parameters delineate whether the economy is stable, has a unique steady state, features hysteresis, or hump-shaped and discontinuous impulse responses.

Moreover, we have used our measurement and empirical strategies to place empirical discipline on these parameters. By so doing, we have been able to provide ballpark figures for the likely quantitative importance of the narratives we have uncovered in our data. Future work may lever alternative data sources and identification strategies to study different narratives or more precisely estimate the parameters that we have studied.

Proposition 2: Important Economic Narratives May Comprise a Very Small Percentage of Popular Talk. Our empirical analysis found that very little of the total variation in narrative discussion is at the aggregate level (See Appendix Table A5). For example, only 1% of the variation in optimism is captured in the aggregate time series. Indeed, even for the 75% percentile of our estimated topic narratives, the fraction of variance explained by the time series is less than 10%. Thus, movements in the intensity with which narratives are discussed appear to be largely a cross-sectional phenomenon. As we have shown, this does not at all mean that aggregate movements are unimportant: measured movements in aggregate optimism can account for between 1/6 and 1/3 of GDP movements over significant economic events. Thus, just as idiosyncratic income risk is much larger than aggregate GDP risk, idiosyncratic narrative variation is much larger than aggregate narrative
variation.

This echoes the observational account of Shiller that important economic narratives may not feature prominently in popular talk and underlines the conclusion that even if movements in aggregate narratives are not a large fraction of what agents think or discuss, they can nevertheless be critical for understanding economic fluctuations.

**Proposition 3:** Narrative Constellations Have More Impact Than Any One Narrative. A central concept in Shiller’s analysis is that of the *narrative constellation*: a grouping of narratives around some basic idea that reinforces contagion. This is a concept about which we are theoretically silent. However, our empirical analysis is designed to allow for the possibility of narrative constellations. Take our analysis of optimism, for example. Our measure does not necessarily capture one coherent economic narrative regarding the strength of the outlook of the economy. What it instead captures is the total sentiment expressed by firms, averaging across the various underlying narratives that they may be adopting at any one instant. We investigate formally the extent to which our data support this by using our more granular narratives as instruments for optimism (see Appendix Table A14, columns 4) and find similar results to our baseline analysis. Moreover, in our quantitative analysis, we studied how many co-evolving latent narratives can manifest as aggregate, sentiment-driven fluctuations in the economy.

Moreover, our analysis of Shiller’s narratives allows us to pick up narrative constellations to the precise extent that Shiller discusses the words comprising the underlying narratives in these constellations in his own analysis. Finally, our topic analysis allows us to pick up narrative constellations to the extent that narratives are used jointly in individual documents. Thus, we do account for the existence of constellations in our measurement and empirical exercises. We view further analysis of this hypothesis as an interesting avenue for future work.

**Proposition 4:** The Economic Impact of Narratives May Change Through Time. Shiller suggests that the impact of economic narratives has the potential to change through time. First, we evaluate this hypothesis in the context of our study in Section 4.1 of how measured optimism affects hiring. Specifically, we consider our baseline regression model

\[
\Delta \log L_{it} = \delta^{OP} \text{opt}_{it} + \gamma_i + \chi_{j(i),t} + \varepsilon_{it}
\]

(276)
Our baseline estimate, in column 1 of Table 1, is $\delta^{OP} = 0.0355$. We now consider a variant in which the coefficient $\delta^{OP}$ varies for each year $1996 \leq \tau \leq 2019$ in our sample:\footnote{The number of firms with data reported for 2019 is very small, so our sample essentially ends in 2018.}

$$\Delta \log L_{it} = \sum_{\tau=1996}^{2019} \delta^{OP}_\tau (\text{opt}_{it} \times I[t = \tau]) + \gamma_i + \chi_{j(i),t} + \varepsilon_{it} \quad (277)$$

We show the coefficient series of $\delta^{OP}_\tau$ graphically in Figure A16. We observe no strong pattern of a trend or business cycle in the coefficient estimates. We interpret this as evidence that the main narrative studied in our empirical analysis has relatively stable effects on decisions over time.

Second, we evaluate whether the contagiousness of optimism has changed through time. One plausible hypothesis is that the rise of the internet and other information technology may have contributed to a more connected knowledge-economy in which there is a faster diffusion of narratives. To do this, we now estimate a variant of our basic regression equation for estimating industry-level contagiousness in which we allow the coefficients, $u$, $r$, and $s$ to vary for each year $1996 \leq \tau \leq 2019$ in our sample:

$$\text{opt}_{it} = \sum_{\tau=1996}^{2019} (u_{\tau} \text{opt}_{i,\tau-1} + s_{\tau} \text{opt}_{j(i),\tau-1} + r_{\tau} \Delta \log Y_{j(i),\tau-1}) I[t = \tau] + \gamma_i + \chi_t + \varepsilon_{it} \quad (278)$$

We can identify time-specific effects only in the industry-specific setting—the corresponding aggregate level regression with time-specific effects is not point identified. We plot the estimated coefficient series of $u_{\tau}$, $r_{\tau}$, and $s_{\tau}$ in Figure A17. We find that stubbornness and contagiousness increase over time, while associativeness is close to flat. This is despite the fact that, as we just showed, the effects of narrative optimism on hiring are stable through time.

Viewed through the lens of our model, these findings—increased contagiousness and stubbornness combined with stable effects on actions—suggests that narrative optimism’s potential to “go viral” and induce dynamic hysteresis in the US economy is increasing over time (see, \textit{e.g.}, Section 7.3). Exploring the macroeconomic implications of this finding may be an interesting avenue for future work. Moreover, this macroeconomic finding underscores the importance of directly testing the hypothesis that the internet and information technology are culpable for the increase in contagiousness and stubbornness; insofar as these changes to narrative propagation could have large effects on macroeconomic dynamics.

**Proposition 5: Truth Is Not Enough to Stop False Narratives.** Shiller emphasizes that narrative epidemics can take place even when patently divorced from fundamentals.
Our theoretical analysis shares this feature. Namely, when the contagiousness of a narrative is high, this can swamp any adverse effects on contagion stemming from outcomes that do not fit the narrative. This is made especially clear by our Proposition 2, in which multiple steady states of narrative penetration can coexist even when one narrative (or even both narratives) are false.

**Proposition 6: Contagion of Economic Narratives Builds on Opportunities for Repetition.** Increased exposure to a narrative is likely to cause agents to pick it up. We find evidence that agents are both more likely to retain a narrative they currently have and that exposure to others holding the same narrative increases the chance that an agent both picks up and retains a narrative. These findings are consistent with Shiller’s hypothesis that oft-repeated narratives are more likely to result in epidemics. However, we do not explore the idea that repeated exposure through time is likely to increase the persistence or contagiousness of a narrative. We view this as an interesting avenue for future work.

**Proposition 7: Narratives Thrive on Attachment: Human Interest, Identity, and Patriotism.** We do not investigate the idea that more interesting narratives are more likely to be contagious in this paper. Studying this idea requires a deeper model for the origins of the stubbornness, associativeness and contagiousness of narratives, which we do not attempt to provide. We merely measure these parameters and take them as given. Of course, this renders our analysis vulnerable to a form of the Lucas critique: if a policymaker attempted to use our estimates as a guide for how they could affect the economy via manipulating narratives, these coefficients could change if they fail to mimic the human interest, identity, or patriotism that drove attachment to the narrative. While this issue is unimportant for our positive analysis, an understanding of the deeper origins of narrative success is an interesting avenue for future work—especially if a policymaker were to seek to guide narratives to achieve certain economic outcomes.

### G.3 The Perennial Economic Narratives: Our Empirical Findings

Shiller (2020) identifies nine perennial economic narratives based on historical analysis. These narratives correspond to:

1. Panic versus Confidence
2. Frugality versus Conspicuous Consumption
3. The Gold Standard versus Bimetallism
4. Labor-Saving Machines Replace Many Jobs
5. Automation and Artificial Intelligence Replace Almost All Jobs
6. Real Estate Booms and Busts
7. Stock Market Bubbles
8. Boycotts, Profiteers, and Evil Businesses
9. The Wage-Price Spiral and Evil Labor Unions

We have measured the presence of these narratives in firm language and studied which of these matters for firm decision-making. Under our baseline LASSO specification, we found that two of these narratives are relevant for firm hiring: Labor-Saving Machines Replace Many Jobs and Stock Market Bubbles. Discussion of both is positively associated with firm hiring (see column 1 of Appendix Table A14). Moreover, we find evidence of contagiousness and stubbornness in firms holding onto these narratives (see Appendix Figure A9).

Figure A1: Time-Series for Positive, Negative, and Their Difference

Notes: Negative and Positive term frequency (first two panels) are cross-sectional averages of z-score transformed variables. The third panel is the cross-sectional average of the difference between the two, or sentiment_{it}. 
Figure A2: Time-Series for Shiller’s Perennial Economic Narratives

Notes: Each panel plots the time-series average of the narrative variable defined for the corresponding chapter of Shiller (2020)’s Narrative Economics. The units are cross-sectional averages of z-score transformed variables.
Figure A3: Time-Series for the Selected LDA Topics

Notes: Each panel plots the time-series average of scores for the corresponding topics, identified by their three most common bigrams. The 11 topics are selected by the LASSO estimation described in Section 4.1, and estimates of which are reported in Table A14. The units in each panel are cross-sectional averages of z-score transformed variables.
**Figure A4:** Heterogeneous Effects of Optimism on Hiring

![Figure A4](image)

*Notes:* In each panel, we show estimates from the regression \( \Delta \log L_{it} = \sum_{q=1}^{r} \beta_q \cdot (\text{opt}_{it} \times X_{qit}) + \gamma_i + \chi_j(t) + \epsilon_{it} \), where \( X_{qit} \) indicates quartile \( q \) of the studied variable: one minus the variable cost share of sales, market capitalization, or book-to-market ratio. In all specifications, we trim the 1% and 99% tails of the outcome variable. Error bars are 95% confidence intervals. Standard errors are double-clustered by firm ID and industry-year.

**Figure A5:** Net Sentiment and Hiring

![Figure A5](image)

*Notes:* In each panel, we show estimates from the regression \( \Delta \log L_{it} = \sum_{q=1}^{10} \beta_q \cdot (\text{sentiment}_{iqt}) + \tau' X_{it} + \gamma_i + \chi_j(t) + \epsilon_{it} \), where \( \text{sentiment}_{iqt} \) indicates decile \( q \) of the continuous sentiment variable. Panel (a) estimates this equation without controls (like column 1 of Table 1); panel (b) adds controls for lagged labor and current and lagged log TFP (like column 2 of Table 1); and panel (c) adds controls for the log book to market ratio, log stock return, and leverage (like column 3 of Table 1). The excluded category in each regression is the first decile of sentiment\(_{it}\). In all specifications, we trim the 1% and 99% tails of the outcome variable. Error bars are 95% confidence intervals. Standard errors are double-clustered by firm ID and industry-year.
Notes: The regression model is Equation 14 (as in Figure 2), but measuring optimism from sales and earnings conference calls. Each coefficient is estimated from a separate projection regression. The outcomes are (a) the log change in TFP, calculated as described in Appendix D.2, (b) the log stock return inclusive of dividends, and (c) changes in profitability, defined as earnings before interest and taxes (EBIT) as a fraction of the previous fiscal year’s variable costs. In all specifications, we trim the 1% and 99% tails of the outcome variable. Each coefficient is estimated from a separate projection regression. Error bars are 95% confidence intervals.
**Figure A7:** Dynamic Relationship between Optimism and Firm Fundamentals, Continuous Sentiment Measurement

Notes: The regression model is Equation 14 (as in Figure 2), but using the continuous variable sentiment, \( t \). Each coefficient is estimated from a separate projection regression. The outcomes are (a) the log change in TFP, calculated as described in Appendix D.2, (b) the log stock return inclusive of dividends, and (c) changes in profitability, defined as earnings before interest and taxes (EBIT) as a fraction of the previous fiscal year’s variable costs. In all specifications, we trim the 1% and 99% tails of the outcome variable. In all specifications, we trim the 1% and 99% tails of the outcome variable. Error bars are 95% confidence intervals. Standard errors are two-way clustered by firm ID and industry-year.
Figure A8: Dynamic Relationship Between Optimism and Financial Variables

Notes: The regression model is Equation 14 (as in Figure 2), but with financial fundamentals as outcomes. Each coefficient is estimated from a separate projection regression. The outcome variables are: (a) the fiscal-year-to-fiscal-year difference in leverage, which is total debt (short-term debt plus long-term debt); (b) sale of common and preferred stock minus buybacks, normalized by the total equity outstanding in the previous fiscal year; (c) short-term debt plus long-term debt issuance, normalized by the total debt in the previous fiscal year; and (d) total dividends divided by earnings before interest and taxes (EBIT). In all specifications, we trim the 1% and 99% tails of the outcome variable. Error bars are 95% confidence intervals. Standard errors are two-way clustered by firm ID and industry-year.
Figure A9: The Contagiousness and Associativeness of Other Identified Narratives

Notes: For each narrative, we estimate the analog of Equation 18. We first transform each continuous narrative loading variable $\hat{\lambda}_{k,it}$ (indexed by narrative identifier $k$, firm $i$, and time period $t$) into a binary indicator for being above the sample median,

$$\hat{\lambda}_{b_{k,it}} = I[\hat{\lambda}_{k,it} \geq \text{med}(\hat{\lambda}_{k,it})] \in \{0, 1\}$$

We then estimate

$$\hat{\lambda}_{b_{k,it}} = u_k \hat{\lambda}_{k,i,t-1} + s_k \overline{\hat{\lambda}}_{b_{k,it}} + r_k \Delta \log Y_{t-1} + \gamma_i + \epsilon_{it}$$

where $\overline{\hat{\lambda}}_{b_{k,it}}$ denotes an aggregate average of the binary variable. The three panels respectively show our estimates, for each narrative $k$, of $(u_k, s_k, r_k)$. The error bars are 95% confidence intervals based on double-clustered (firm and industry-year) standard errors.
Figure A10: Comparing the Hiring Effects and Associativeness of Narratives

Notes: For each narrative, we estimate the analog of Equation 12 with \( \hat{\lambda}_{k,it} \), a binary indicator for the narrative weight \( k \) being above the sample median (for firm \( i \) at time \( t \)), in place of \( \text{opt}_{it} \) (see the notes for Figure A9 for details about constructing these variables). The \( x \)-axis of this figure shows the estimated hiring coefficients \( \delta^k \) and the \( y \)-axis shows the estimated associativeness coefficients \( r^k \) (see Figure A9). Each point is labeled by its running short name, and the solid line is a best-fit trend based on these fourteen points.
Figure A11: Fundamental and Optimism Shocks That Explain US GDP

Notes: This figure shows the shocks that rationalize movements in optimism and detrended real GDP in recent US history, as analyzed in Section 7.2. The solid line is the exogenous process for fundamental output and the dashed line is the sequence of shocks in narrative evolution. The dashed line is rescaled by $\delta^{OP}(1 - \omega)^{-1}$ to be, up to linear approximation of $f$, in units of output.
**Figure A12:** Variance Decomposition for Different Values of Stubbornness and Contagiousness, No Optimism Shocks

**Notes:** This Figure replicates Figure A12, with a different color bar scale, in the variant model with no exogenous shocks to optimism. Calculations vary $u$ and $s$, holding fixed all other parameters at their calibrated values. The shading corresponds to the fraction of variance explained by optimism, or Share of Variance Explained, defined in Equation 56. The plus is our calibrated value of $(u, s)$, corresponding to a variance share 4.7%, and the dotted line is the boundary of a 95% confidence set. The dots are calibrated values for other narratives from Figure A9. The dashed line is the condition of extremal multiplicity from Corollary 3 and Equation 44.
**Figure A13:** Tendency Toward Extremal Optimism

*Notes:* This Figure plots, in color, the fraction of time that optimism $Q_t$ lies outside of the range $[0.25, 0.75]$ and therefore concentrates at extreme values. Calculations vary $u$ and $s$, holding fixed all other parameters at their calibrated values. The plus is our calibrated value of $(u, s)$, corresponding to an extremal share of 0%, and the dotted line is the boundary of a 95% confidence set. The dots are calibrated values for other narratives from Figure A9. The dashed line is the condition of extremal multiplicity from Corollary 3 and Equation 44.
Figure A14: Variance Contributions Toward Emergent Optimism

Notes: This Figure plots each granular narrative’s contribution toward the variance of emergent optimism in the constellations model (Section 7.4) against the condition number for extremal multiplicity (Equation 57). Each dot corresponds to one of the thirteen granular narratives.

Figure A15: Time-Varying Relationship Between Optimism and TFP

Notes: Each dot is a coefficient $\beta_{\tau}$ estimated from Equation 186, corresponding to a year-specific effect of binary optimism (opt$_{it}$) on log TFP (log $\hat{\theta}_{it}$). The outcome variable is firm-level log TFP, log $\theta_{it}$, and the regressors are indicators for binary optimism interacted with year dummies. In the regression, we trim the 1% and 99% tails of the outcome variable. Error bars are 95% confidence intervals, based on standard errors clustered by firm and industry-time.
Figure A16: Time-Varying Effects of Narrative Optimism on Hiring

Notes: Each dot is a coefficient $\delta_{\tau}^{OP}$ estimated from Equation 277, capturing a year-specific effect of binary optimism ($opt_{it}$) on hiring ($\Delta \log L_{it}$). Error bars are 95% confidence intervals, based on standard errors clustered by firm and industry-year.

Figure A17: Time-Varying Stubbornness, Contagiousness, and Associativeness of Narrative Optimism

Notes: Each dot is a coefficient estimated from Equation 278, and error bars are 95% confidence intervals, based on standard errors clustered by firm and industry-year. Panel (a) plots the stubbornness coefficients on $opt_{i,t-1}$, $u_{\tau}$; panel (b) plots the contagiousness coefficients on $opt_{j(i),t-1}$, $s_{\tau}$; and panel (c) plots the associativeness coefficients on $\Delta \log Y_{j(i),t-1}$, $r_{\tau}$.

<td>0.043</td>
<td>0.088</td>
<td>-0.034</td>
</tr>
<tr>
<td>Shiller Narratives (75th)</td>
<td>0.884</td>
<td>0.541</td>
<td>0.422</td>
<td>0.246</td>
</tr>
</tbody>
</table>

Notes: Calculated with annual data from 1995 to 2019 for optimism and the topics, and 1995 to 2017 for the Shiller Narratives. $u_t$ is the US unemployment rate. The quantiles for Shiller Narratives and Topic Narratives are the quantiles of the distribution of the variable in that column within each set of narratives.

Table A5: Variance Decomposition of Narratives

<table>
<thead>
<tr>
<th>Narrative $N_{it}$</th>
<th>Fraction Variance Explained By Means</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>$t$</td>
</tr>
<tr>
<td>Net Sentiment</td>
<td>0.014</td>
</tr>

<td>1.691</td>
<td>2.151</td>
</tr>
<tr>
<td>$\delta^{OP*} (\lambda = 1)$</td>
<td>0.0126</td>
<td>0.0165</td>
</tr>
</tbody>
</table>

Notes: This table summarizes the coefficient stability test described in Appendix E.1. Panel A shows estimates of Equation 241, with and without controls for current and lagged log TFP and lagged log labor. The estimate in column 1 differs from that in column 1 of Table 1 due to restricting to a common sample in columns 1 and 2. The $R^2$ values are for the model after partialing out fixed effects, and hence correspond with unreported “within-$R^2$” values in Table 1. Panel B prints the two statistics of Oster (2019). In column 1, we set $\bar{R}^2$ equal to our estimated value of 0.459, calculated as described in the text from an “over-controlled” regression of current hiring on lagged controls and future hiring and productivity. In column 2, we use $\bar{R}^2$ given by three times the $R^2$ in the controlled hiring regression. The first row ($\lambda^* (\delta^{OP} = 0)$) reports the degree of proportional selection that would generate a null coefficient. The second row ($\delta^{OP*} (\lambda = 1)$) is the bias corrected effect assuming that unobservable controls have the same proportional effect as observable controls.
Table A7: Narrative Optimism Predicts Hiring, With More Adjustment-Cost Controls

</tbody>
</table>

Notes: This Table replicates the analysis of Table 1 with alternative standard error constructions. Standard errors in parentheses are two-way clustered by firm ID and industry-year; those in square brackets are two-way clustered by firm ID and year; and those in braces are two-way clustered by industry and year. For columns 1-4, the regression model is Equation 12 and the outcome is the log change in firms’ employment from year $t - 1$ to $t$. The main regressor is a binary indicator for the optimistic narrative, defined in Section 3.2. In all specifications, we trim the 1% and 99% tails of the outcome variable. In column 5, the regression model is Equation 13, the outcome is the log change in firms’ employment from year $t$ to $t + 1$, and control variables are dated $t + 1$.

</tr>
<tr>
<td>First-stage $F$</td>
<td>773</td>
<td>478</td>
<td>366</td>
<td>3,597</td>
</tr>
</tbody>
</table>

Notes: All columns come from a two-stage-least-squares (2SLS) estimate of Equation 12, using $opt_{i,t-1}$ as an instrument for $opt_{it}$. Specifically, the structural equation is

$$\Delta \log L_{it} = \delta^{OP} \cdot opt_{it} + \gamma_i + \chi_{j(i),t} + \tau'X_{it} + \varepsilon_{it}$$

the endogenous variable is $opt_{it}$ and the excluded instrument is $opt_{i,t-1}$. In the last row, we report the first-stage $F$ statistic associated with this equation. In all specifications, we trim the 1% and 99% tails of the outcome variable. Standard errors are two-way clustered by firm ID and industry-year.

</tbody>
</table>

**Notes:** The regression model is Equation 15. The outcome in columns 1 and 2 is a binary indicator for ex post optimism in guidance, and the outcome in columns 3 and 4 is the difference between the log guidance value and the log realized sales. opt<sub>it</sub> is the binary measure of narrative optimism, and sentiment<sub>it</sub> is the underlying continuous measure from which opt<sub>it</sub> is constructed. In all specifications, we trim the 1% and 99% tails of the outcome variable. Standard errors are two-way clustered by firm ID and industry-year.

Notes: This Table replicates the analysis of Table 4 with alternative standard error constructions. Standard errors in parentheses are two-way clustered by firm ID and industry-year; those in square brackets are two-way clustered by firm ID and year; and those in braces are two-way clustered by industry and year. Aggregate, industry, and peer average optimism are averages of the narrative optimism variable over the respective sets of firms. Industry output growth is the log difference in sectoral value-added calculated from BEA data, linked to two-digit NAICS industries.

</tbody>
</table>

Notes: The regression model is a variant of Equation 20 for column 1-4, and an analogous variant of industry-level specification for columns 5-7 (i.e., Equation 19 with past and future controls), with the continuous variable sentiment$_{it}$ (and averages thereof) substituted for binary optimism. Columns 1 and 5 are “baseline estimates” corresponding, respectively, with columns 1 and 3 of Table A16. The added control variables are two leads, two lags, and the contemporaneous value of: real GDP growth (columns 2-4), industry-level output growth (columns 3-4 and 6-7), and firm-level TFP growth (columns 4 and 7). In all specifications, we trim the 1% and 99% tails of sentiment$_{it}$. Standard errors are two-way clustered by firm ID and industry-year.

<td>1.0</td>
</tr>
<tr>
<td>High ϵ</td>
<td>1.0</td>
</tr>
<tr>
<td>Decreasing RtS</td>
<td>0.75</td>
</tr>
</tbody>
</table>

**Notes:** This table summarizes the quantitative results under alternative calibrations of the macroeconomic parameters, which we report along side their implied complementarity \(\omega\) and demand multiplier \(\frac{1}{1-\omega}\). We report four statistics as the “results” in the last four columns. The first two are the fraction of output variance explained statically, \(\hat{c}_Q(0)\), and at a one-year horizon, \(\hat{c}_Q(1)\), by optimism. The second two are the fraction of output losses in the 2000-02 downturn and 2007-09 downturn explained by fluctuations in narrative optimism. Baseline corresponds to our main calibration. High \(\psi\) increases the inverse Frisch elasticity to 2.5, or decreases the Frisch elasticity to 0.4. High \(\gamma\) increases the curvature of consumption utility (indexing income effects in labor supply) from 0.0 to 1.0. Empirical Multiplier adjusts \(\psi\) to match an output multiplier in line with estimates from Flynn, Patterson, and Sturm (2021). Calibrated multiplier adjusts \(\psi\) to match our own calculation of the multiplier in our setting in Appendix F.3. High \(\epsilon\) increases the elasticity of substitution from 2.6 to 5.0, with \(\psi\) adjusting to hold fixed the multiplier. Decreasing RtS reduces the returns-to-scale parameter \(\alpha\) from 1.0 to 0.75, with \(\psi\) adjusting to hold fixed the multiplier.

</table>

Notes: The regression model is Equation 242 for columns 1-3, and Equation 243 for column 4. The outcome is the log change in firms’ employment. $opt_{it}$ is a binary indicator for the optimistic narrative, defined in Section 3.2. ChangeCEO$_{it}$ is a binary indicator for whether firm $i$ changed CEO in fiscal year $t$ due to death, illness, personal issues or voluntary retirement. In all specifications, we trim the 1% and 99% tails of the outcome variable. Standard errors are two-way clustered by firm ID and industry-year.

| First-stage $F$ | — | — | 99.1 | — | — | 262.3 |

**Notes:** This table estimates Equations 18 and 19, respectively modeling the spread of optimism at the aggregate and industry level, using granular identification of spillovers (contagiousness). $\overline{\text{opt}}_{t-1}^{sw}$ and $\overline{\text{opt}}_{j(i),t-1}^{sw}$ are sales-weighted averages of aggregate and industry optimism, respectively. $\overline{\text{opt}}_{t-1}^{g,sw}$ and $\overline{\text{opt}}_{j(i),t-1}^{g,sw}$ are (lagged) sales-weighted averages of the non-fundamentally-predictable components of firm-level optimism in the aggregate and in the industry, respectively, as explained in Appendix E.5. In columns 3 and 6, we use the granular variables as instruments for the raw sales-weighted averages. Standard errors are two-way clustered by firm ID and industry-year.
Table A28: Multiplier Calibrations via Under-Controlled Regressions of Hiring on Optimism

<td>65,508</td>
</tr>
<tr>
<td>$R^2$</td>
<td>0.259</td>
<td>0.207</td>
<td>0.216</td>
</tr>
</tbody>
</table>

Notes: The regression models are introduced in Appendix F.3. The first column replicates Column 1 of Table 1. The second two columns remove the industry-by-time FE and control for the contemporaneous and lagged value of seasonally adjusted log TFP, respectively with and without capacity utilization adjustment, as reported by the updated data series of Fernald (2014). The sample size is lower in columns 2 and 3 due to the band-pass filtering being impossible for the last part of the sample. The remaining rows give the implied complementarity $\omega$ and demand multiplier $\frac{1}{1-\omega}$, by comparing the coefficients with that of column 1 and applying the formula in Equation 275. Standard errors are double-clustered by industry-year and firm ID.
